Seafood Watch® Criteria for Fisheries

Public comment period – 1

Introduction
The Monterey Bay Aquarium is requesting and providing an opportunity to offer feedback on the Seafood Watch Fisheries Assessment Criteria during our current revision process. Before beginning this review, please familiarize yourself with all the documents available on our Standard review website.

Providing feedback, comments and suggestion
This document contains the current version of the Seafood Watch criteria. “Guidance for public comment” sections have been inserted and highlighted, and various general and specific questions have been asked throughout. In certain sections, proposed changes have been noted using redlining for proposed new text and strikethrough for proposed deletion. Narrative descriptions and rationale for proposed changes are also described in the respective comment sections. Seafood Watch welcomes feedback and particularly suggestions for improvement on any aspect of the criteria. Please provide feedback, supported by references wherever possible in any sections of the criteria of relevance to your expertise.

Seafood Watch Ratings
The Seafood Watch Criteria for Fisheries are used to produce assessments for wild-capture fisheries resulting in a Seafood Watch rating of Best Choice (green), Good Alternative (yellow), or Avoid (red). The assessment criteria are used to determine a final numerical score as well as numerical subscores and color ratings for each criterion. These scores are translated to a final Seafood Watch color rating according to the methodology described in the table below. The table also describes how Seafood Watch defines each of these categories. The narrative descriptions of each Seafood Watch color rating category, and the guiding principles listed below, compose the framework the criteria are based on, and should be considered when providing feedback on any aspect of the criteria.

| Best Choice | Final Score >3.2, and no Red Criteria, and no Critical scores | Wild-caught and farm-raised seafood on the “Best Choice” list are ecologically sustainable, well managed |

1 Each criterion is scored from 1 to 5 based on subfactor scores, as described in the document below. Criteria scoring <= 2.2 are considered “red” criteria. The final numerical score for the fishery is calculated as the geometric mean of the four Scores (Criterion 1, Criterion 2, Criterion 3, Criterion 4).

2 Very severe conservation concerns receive “critical” scores, which result in an Avoid recommendation.
and caught or farmed in ways that cause little or no harm to habitats or other wildlife. These operations align with all of our guiding principles.

| Good Alternative | Final score >2.2, and neither Harvest Strategy (Factor 3.1) nor Bycatch Management Strategy (Factor 3.2) are Very High Concern, and no more than one Red Criterion, and no Critical scores, and does not meet the criteria for Best Choice (above) | Wild-caught and farm-raised seafood on the “Good Alternative” list cannot be considered fully sustainable at this time. They align with most of our guiding principles, but there is either one conservation concern needing substantial improvement, or there is significant uncertainty associated with the impacts of this fishery or aquaculture operations. |
| Avoid | Final Score <=2.2, or either Harvest Strategy (Factor 3.1) or Bycatch Management Strategy (Factor 3.2) is Very High Concern, or two or more Red Criteria, or one or more Critical scores. | Wild-caught and farm-raised seafood on the “Avoid” list are caught or farmed in ways that have a high risk of causing significant harm to the environment. They do not align with our guiding principles, and are considered unsustainable due to either a critical conservation concern, or multiple areas where improvement is needed. |

1. **Follow the principles of ecosystem-based fisheries management**
   The fishery is managed to ensure the integrity of the entire ecosystem, rather than solely focusing on maintenance of single species stock productivity. To the extent allowed by the current state of the science, ecological interactions affected by the fishery are understood and protected, and the structure and function of the ecosystem is maintained.

2. **Ensure all affected stocks are healthy and abundant**
   Abundance, size, sex, age and genetic structure of the main species affected by the fishery (not limited to target species) is maintained at levels that do not impair recruitment or long-term productivity of the stocks or fulfillment of their role in the ecosystem and food web. Abundance of the main species affected by the fishery should be at, above, or fluctuating around levels that allow for the long-term production of maximum sustainable yield.

3. **Fish all affected stocks at sustainable levels**
   Fishing mortality for the main species affected by the fishery should be appropriate given current abundance and inherent resilience to fishing while accounting for scientific uncertainty, management uncertainty, and non-fishery impacts such as habitat degradation. The cumulative fishing mortality experienced by affected species must be at or below the level that produces maximum sustainable yield for single-species fisheries on typical species that are at target levels. Fishing mortality may need to be lower than the level that produces maximum sustainable yield in certain cases such as multispecies fisheries, highly vulnerable species, or fisheries with high uncertainty. For species that are depleted below target levels, fishing mortality must be at or below a level that allows the species to recover to its target abundance.

4. **Minimize bycatch**

---

3 Because effective management is an essential component of sustainable fisheries, Seafood Watch issues an Avoid recommendation for any fishery scored as a Very High Concern for either factor under Management (Criterion 3).

4 “Affected” stocks include all stocks affected by the fishery, no matter whether target or bycatch, or whether they are ultimately retained or discarded.
Seafood Watch defines bycatch as all fisheries-related mortality or injury other than the retained catch. Examples include discards, endangered or threatened species catch, pre-catch mortality and ghost fishing. All discards, including those released alive, are considered bycatch unless there is valid scientific evidence of high post-release survival and there is no documented evidence of negative impacts at the population level.

The fishery optimizes the utilization of marine resources by minimizing post-harvest loss and by efficiently using marine resources as bait.

5. **Have no more than a negligible impact on any threatened, endangered or protected species**
   The fishery avoids catch of any threatened, endangered or protected (ETP) species. If any ETP species are inadvertently caught, the fishery ensures and can demonstrate that it has no more than a negligible impact on these populations.

6. **The fishery is managed to sustain the long-term productivity of all affected species.**
   Management should be appropriate for the inherent resilience of affected marine life and should incorporate data sufficient to assess the affected species and manage fishing mortality to ensure little risk of depletion. Measures should be implemented and enforced to ensure that fishery mortality does not threaten the long-term productivity or ecological role of any species in the future.
   The management strategy has a high chance of preventing declines in stock productivity by taking into account the level of uncertainty, other impacts on the stock, and the potential for increased pressure in the future.
   The management strategy effectively prevents negative population impacts on bycatch species, particularly species of concern.

7. **Avoid negative impacts on the structure, function or associated biota of marine habitats where fishing occurs.**
   The fishery does not adversely affect the physical structure of the seafloor or associated biological communities.
   If high-impact gears (e.g. trawls, dredges) are used, vulnerable seafloor habitats (e.g. corals, seamounts) are not fished, and potential damage to the seafloor is mitigated through substantial spatial protection, gear modifications and/or other highly effective methods.

8. **Maintain the trophic role of all marine life**
   All stocks are maintained at levels that allow them to fulfill their ecological role and to maintain a functioning ecosystem and food web, as informed by the best available science.

9. **Do not result in harmful ecological changes such as reduction of dependent predator populations, trophic cascades, or phase shifts**
   Fishing activities must not result in harmful changes such as depletion of dependent predators, trophic cascades, or phase shifts.
   This may require fishing certain species (e.g. forage species) well below maximum sustainable yield and maintaining populations of these species well above the biomass that produces maximum sustainable yield.

10. **Ensure that any enhancement activities and fishing activities on enhanced stocks do not negatively affect the diversity, abundance or genetic integrity of wild stocks**
    Any enhancement activities are conducted at levels that do not negatively affect wild stocks by reducing diversity, abundance or genetic integrity.
    Management of fisheries targeting enhanced stocks ensure that there are no negative impacts on the wild stocks, in line with the guiding principles described above, as a result of the fisheries.
    Enhancement activities do not negatively affect the ecosystem through density dependent competition or any other means, as informed by the best available science.
Seafood Watch Criteria for Fisheries

**Public comment guidance** - This section contains the standards preamble. We are not requesting specific feedback on this section, but feel free to comment on this general background information.

**Comment**

The Monterey Bay Aquarium is committed to inspiring conservation of the oceans. To this end, Seafood Watch®, a program of the Monterey Bay Aquarium, researches and evaluates the sustainability of fisheries products and shares these seafood recommendations with the public and other interested parties in several forms, including regionally specific Seafood Watch pocket guides, smartphone apps and online at [www.seafoodwatch.org](http://www.seafoodwatch.org).

The criteria laid out in this document allow assessment of the relative sustainability of wild-capture fisheries according to the guiding principles and conservation ethic of the Monterey Bay Aquarium. Farmed seafood sources are evaluated with a different set of criteria.

Seafood Watch® defines “sustainable seafood” as seafood from sources, whether fished or farmed, that can maintain or increase production without jeopardizing the structure and function of affected ecosystems. Sustainable wild-capture fisheries should ensure that the abundance of both targeted and incidentally caught species is maintained in the long term at levels that allow the species to fulfill its ecological role, while the structure, productivity, function and diversity of the habitat and ecosystem are all maintained. A management system should be in place that enforces all local, national and international laws to ensure long-term productivity of the resource and integrity of the ecosystem by adhering to the [precautionary approach](http://www.seafoodwatch.org) and responding to changing circumstances.

**Scope**

Seafood Watch® recommendations apply to a single stock or species caught in a single fishery as defined by gear type, region and management body.
**Public comment guidance** – The contents page provides an opportunity to see the full list of fisheries criteria. We welcome feedback on this list at the broad level of inclusion; i.e. are these the correct impact categories to be considering in an assessment of fisheries sustainability? Note that Seafood Watch does not currently intend to assess socioeconomic impacts and defers to other organizations with specific expertise, and that we are developing criteria to assess greenhouse gas (GHG) emissions associated with up-to-the-dock or farmgate production of seafood products from fisheries and aquaculture (available for public comment in a separate document).

Public Comment Guidance for Criterion 1

Overview – Criterion 1 is used for scoring the impacts of the fishery on the stock being assessed. It incorporates both the current abundance of the stock (i.e., whether it is overfished), and the fishing mortality (i.e., whether overfishing is occurring). The combination of scores for abundance and fishing mortality determines the score for Criterion 1. In addition, the same factors are assessed for all other major species caught in the fishery (including other targeted species as well as bycatch). These other species are assessed under Criterion 2, but the factors are identical. Therefore, the factors detailed below have a particularly significant impact on the scoring of each fishery. These factors are also inherently complex as they take into account multiple considerations, including not just abundance and fishing mortality, but also inherent vulnerability of the species, uncertainty in the stock assessment or other data used to determine abundance and fishing mortality, and the degree to which a fishery is one of the substantial contributors to the cumulative fishing mortality experienced by a species.

Because of its significance and complexity, many of the proposed changes for this criterion review focus on the structure and language in Criterion 1.

Specific proposals are available under each of Factor 1.1 and Factor 1.2. Please see these respective sections and provide comments there.

Feedback no specific proposals for Factors 1.2 and 1.3 should be provided in the boxes under these respective factors. Please provide any general comments or suggestions regarding the structure of Criterion 1 below.

Comments

Guiding principles

*The stock* is healthy and abundant. Abundance, size, sex, age and genetic structure should be maintained at levels that do not impair the long-term productivity of the stock or fulfillment of its role in the ecosystem and food web.

Fishing mortality does not threaten populations or impede the ecological role of any marine life. Fishing mortality should be appropriate given current abundance and inherent vulnerability to fishing while accounting for scientific uncertainty, management uncertainty, and non-fishery impacts such as habitat degradation.

Assessment instructions

Evaluate Factors 1.1–1.3 under Criterion 1 to score the stock for which you want a recommendation. Evaluate Factors 2.1–2.4 under Criterion 2 to score all other main species in the fishery, including both

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
bycatch and retained species as well as any overfished, depleted, endangered, threatened or other species of concern that are regularly caught in the fishery.

Note that if wild stocks are assessed only in combination with hatchery-raised populations, the health of the wild stock cannot be considered better than “moderate concern”.

Factor 1.1 Inherent Vulnerability

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
Public Comment Guidance

Overview
Factor 1.1 is used to score the inherent vulnerability of species caught in the fishery, which is then used in Factor 1.2 to determine whether a species’ abundance is considered a moderate or high concern, when stock status is unknown. We are proposing to integrate the current Factor 1.1 into Factor 1.2.

Specific Proposed Changes
Factor 1.1 is currently assessed for all species to determine if they are “high”, “medium”, or “low” vulnerability; however, this factor is only relevant to the scoring if the stock status of the species is unknown, and then only if it is of “high” vulnerability (i.e. “medium” and “low” vulnerability species are scored the same). This results in unnecessary work for the assessor and causes confusion in the review process. We are proposing to combine Factor 1.1 with Factor 1.2 so that vulnerability will be assessed only for those species with unknown stock status. In addition, we are proposing several changes to how vulnerability will be assessed.

The text in Factor 1.1 below has been marked with strikethrough to denote that it will be removed from this section (and moved to Factor 1.2). Details and rationale for these proposed changes can be found under Factor 1.2, as that is where the assessment instructions will now reside.

Feedback
Please provide feedback below on the option of integrating Factor 1.1 with Factor 1.2. To provide feedback on the specific language used in this factor, please see Factor 1.2 with the information now resides.

Questions:
1. Do you believe it is a good idea to integrate Factor 1.1 with Factor 1.2, and score inherent vulnerability only when it will affect the overall score (i.e. when stock abundance is unknown)? Why or why not?

Comments: I agree that Vulnerability should not be a stand-alone factor. In fact, I think vulnerability assessments are somewhat fraught. While the common belief is that low productivity stocks are inherently more vulnerable, high productivity stocks that have extremely high variability in stock size are also “vulnerable” in the sense that their numbers can become extremely low. Witness the herring and sardine collapses of the 1960s-80s. Some stocks almost disappeared, or remained at extremely low levels for long periods of time during which they may have actually been at risk of extinction.

For example, California sardine The California sardine population was heavily fished during the 1930s to 1950s and had essentially “crashed” by about 1964. From then until 1983, the median population size was about 5,000 mt, about 0.12% of the high of 4.2 million mt. In terms of numbers, the decline was from about 21 billion individuals to about 25 million individuals. Even though the lower number of individuals may still seem quite high, the fish were essentially in one “school” that could have been virtually eliminated by piscivorous whales or purse seiners (if whales hadn’t been decimated and purse seiners banned from fishing).
Some of the herring stocks in the North Atlantic remained at dangerously low levels for 2-3 decades or more.

While I agree with combining vulnerability with other factors and/or only considering it when there is little or no other information available, I wonder if it isn’t more appropriate to combine it with the fishing mortality factor rather than the biomass factor? I think that virtually all marine species can, theoretically, be harvested sustainably – it’s just that harvest rates and catches may need to be extremely low in some cases. In other words, low F’s should be applied to vulnerable species.

To me, a stock is “vulnerable” - to overfishing, becoming overfished/depleted, or even to becoming endangered – when F is high relative to M (e.g. F > M, as a general rule of thumb).

My final comment on this issue relates to your vulnerability table (now under 1.2). Some of these factors may be more useful than others, and some may not be particularly useful. The latter category includes fecundity. By necessity, fecundity has adapted over time to the reproductive strategy of the species. Producing large number of small eggs that are vulnerable to a myriad of other species and life history stages is not necessarily better than producing a smaller number of large eggs that have relatively high survival. For a similar reason, I question whether a live bearing strategy makes a species inherently more vulnerable than being a broadcast spawner? I know there is literature that suggests this, but I can think of some instances where it might not be the case. For example I conducted an evaluation (with others) for Banggai cardinalfish a few years back; the males are mouth brooders and some scientists suggested that this implied that they must be highly vulnerable. Yet, they only live for about 18 months in the wild, which means the number and survivability of the young must have evolved to compensate for such a short life span. In fact, the extremely high M would suggest that they have very low vulnerability. (There are other reasons they are might be vulnerable though – they have an extremely limited distribution and are exploited for the aquarium trade throughout their distribution).

Under the category of “Reproductive strategy” for invertebrates, I think being a broadcast spawner can make a species highly vulnerable if it is sessile (although I suppose you could call that an Allee or depensatory effect).

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
**Goal:** Ensure fishing mortality and other management measures are appropriate for the inherent vulnerability of the stock.

**Instructions:** Where available, Seafood Watch uses FishBase “vulnerability” scores to assign a score for inherent vulnerability of the stock. The FishBase vulnerability score is derived from Cheung et al. (2005) and is found at www.fishbase.org on the species’ page.

<table>
<thead>
<tr>
<th>FishBase vulnerability score</th>

<tr>
<td>36–55</td>
<td>Moderate inherent vulnerability</td>
</tr>
<tr>
<td>56–100</td>
<td>High inherent vulnerability</td>
</tr>
</tbody>
</table>

Some fish and all invertebrates do not have a FishBase score. For these species, use the steps below (modified from the MSC Productivity Attributes from PSA Analysis used in Risk Based Framework. Source (MSC 2009)).

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Step 1: Assign a score for each productivity attribute based on the table below. Scores will be 1, 2 or 3 for each attribute you select (if an attribute falls in between categories, intermediate scores (e.g. 2.5) may be used if well justified). Once all scores are selected, average the values to arrive at an overall vulnerability score (from 1–3). If any attribute is unknown or any value falls into an NA category (for moderate to high fecundity), that attribute is omitted from the average.

Public comment guidance

Overview – Factor 1.2 scores the abundance of species caught in the fishery, including whether it is above or below limit and target reference points, if known, or classified as overfished, threatened or endangered. The score from Factor 1.2, combined with Factor 1.3 (which assesses fishing mortality), determines the score for Criterion 1 – Impact on the Species Under Assessment.

Specific Proposed Changes

We are proposing several changes to Factor 1.2 in order to 1) simplify and streamline its assessment, and 2) allow for consideration of circumstances that are not well captured by the current criteria. Specific proposed changes and their rationale are described below. The text changes proposed can be seen below in red (added text) and strikethrough (deleted text). Note: the text from Factor 1.1 has been moved to this section, but is not shown in red except where we are proposing changes to the text that was previously in Factor 1.2.

Inherent vulnerability – As described under Factor 1.1 in this document, we are proposing integrating the inherent vulnerability calculation (currently under Factor 1.1) with Factor 1.2, as inherent vulnerability is only used in conjunction with scoring abundance (when abundance is unknown). This will help streamline assessments and avoid unnecessary work and confusion associated with assessing inherent vulnerability when (in most cases) it does not affect the score.

In addition, we are proposing a change to how inherent vulnerability is calculated. Our current criteria have two methods of assessing inherent vulnerability – 1) using fishbase whenever a fishbase vulnerability score is available, and 2) using a productivity scoring table (based on Productivity-Susceptibility Analysis methodology) for invertebrates or any fish which do not have a fishbase vulnerability score. However, in practice we have found that the fishbase score is often quite conservative compared both to the PSA score and to expert opinion. We conducted a detailed analysis to compare various published PSA approaches (productivity attributes only; susceptibility is considered under 1.3) with expert opinion and based on the results, we are proposing a combination approach that uses the fishbase score as an initial filter (as fishbase score is always conservative according to our assessment) and then further scores those species that are high vulnerability according to fishbase, using the productivity attributes from the PSA methodology published in Field et al. 2010 to determine their final vulnerability score. This methodology was found in our assessment to have the closest correlation with species-specific expert input.

Reducing table from five to four classification tiers (removal of “very high concern” category) - Currently, Factor 1.2 has five classification tiers ranging from “very high concern” (score of 1/5) to “very low concern” (score of 5/5). Stocks classified as “overfished” are classified as “high concern”, while those that are endangered or threatened are classified as “very high concern”. In practice, we have found that this distinction is not always as clear as it needs to be to support the differential scoring. For example, some species (e.g. Pacific bluefin tuna) are very severely depleted (e.g. below 5% of virgin biomass) but are not listed as endangered or threatened, perhaps because the information on their status is relatively new, or for political reasons. Others may be listed as endangered but new data shows that their population is recovering, yet there has not been enough time and/or enough data for delisting. These species are still of concern, but not any higher concern than severely

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
depleted species that are not listed. Finally, differences in procedures for listing species in different states and nations, combined with the often poor fit of international classification systems (e.g. IUCN) with finfish species, further complicates the distinction. As a result, we propose combining these categories.

The change from 5 to 4 categories will streamline the assessments, but potential changes to scoring for overfished and endangered species needs to be considered. Scoring is always scaled linearly from 1 to 5, with the lowest category scored at a 1 (with the exception of critical concerns); therefore, the proposal adjusts the scoring accordingly. While this may appear to result in lower scores, we are proposing concomitant changes to the scoring of Factor 1.3, and the scoring must be considered together. To illuminate this complex issue, we have provided a separate comment section with guidance and examples specifically on scoring of Criterion 1, and ask for your feedback on the scoring there. In this section, please provide any comments on the proposal to group overfished and endangered/threatened species together in the “high concern” category.

**Consideration of trend data for species below target biomass levels** – In the current criteria, stocks that are above a limit reference point but below a target reference point are scored a “low concern”. This is to avoid overly penalizing fisheries that have rebuilding stocks, especially when rebuilding may take time but the fishery has already implemented strong management, and to account for the consideration that even in well managed fisheries, stocks will fluctuate around target reference points but should not go below limit reference points. However, we have found this structure is not appropriate for the situation in which a stock is below target reference point but showing a clear declining trend, approaching the limit reference point. In such cases, we feel higher caution is warranted. As such, we are proposing that stocks in this situation are classified as a “moderate concern”.

**Classifying high vulnerability, data-poor species** – In the current criteria, high vulnerability species are classified as high concern under 1.2 if stock status is completely unknown. If there are data demonstrating that the stock is not overfished, they are classified as a low concern. We have found that these criteria do not account for cases where there may be some data indicating the species is not depleted (and therefore it is not appropriate to score as a “high concern”), but the data are not sufficient (due to high uncertainty, lack of stock assessment, etc.) to conclude the stock is necessarily a “low concern”. We are proposing adding guidance to the criteria to allow for scoring as a “moderate concern” in these cases.

**Feedback:** please comment below on these proposed changes as well as any other comments on this factor (including comments on inherent vulnerability). Please see specific questions for public consultation below as well.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Comments on above proposed changes

Questions for public consultation

1. Do you think it is appropriate to score inherent vulnerability: a) only when stock status is unknown (as proposed here) <or, perhaps more appropriately, when fishing mortality is unknown – see my earlier comments on vulnerability>, b) for all assessed species <suggest omitting completely if both F and B are known>, or c) not at all <possibly, as I question its overall utility; however, it may be provide some information if there’s virtually nothing else>?

2. Please provide any thoughts on the proposal for scoring inherent vulnerability. See my earlier comments on the table. While I question whether low productivity makes a species inherently more vulnerable than very high productivity, this does seem to be the current dogma (to which I have also contributed). If that is the assumption you still want to go with, then I suggest that the one variable in your table that is way more important than any of the others; viz natural mortality – which is highly correlated with productivity – and should somehow be weighted more than the other variables. In a sense, it already is, because you also include the average maximum age which, in turn, is highly correlated with M.

Why is M not applicable for invertebrates?

3. In some cases, we have used expert opinion to override the fishbase score where that score was deemed to be inaccurate for a given species. Even though using the fishbase score as a filter combined with the Field et al 2010 productivity metric is expected to provide better correspondence to expert opinion, this method for scoring vulnerability may still disagree with expert opinion in some cases. In such cases, do you believe it is ever advisable to override the vulnerability score based on expert opinion? <Yes, the data in Fish base are of variable quality> If so, in what circumstances would you seek expert opinion and use it as the basis of the ranking rather than using the method defined in the criteria?

4. The NMFS methodology (currently under development/not yet finalized) uses a combination of sensitivity attributes and climate factors as expert opinion to assess vulnerability of a fish stock to climate change, and is referred to as the “Fish Stock Climate Vulnerability Assessment”. A description of the methodology can be found here: http://www.st.nmfs.noaa.gov/ecosystems/climate/activities/assessing-vulnerability-of-fish.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
stocks.

A 1 page fact sheet can be found here:
http://www.st.nmfs.noaa.gov/Assets/ecosystems/climate/documents/Fish_Stock_Climate_Vulnerability_Assessment.pdf

Do you feel this index, once developed, should be integrated into our assessment of inherent vulnerability? If so, how? I have not had time to investigate this, but I’m sure it will be worth considering!

5. We are hoping to provide further clarification and guidance on what level and type of uncertainty should be considered evidence that a stock should be scored “low” rather than “very low”, or “moderate” rather than “low concern”. Considerations may include age of the stock assessment, availability of fishery independent vs fishery dependent (e.g. CPUE) data, scientific controversy, etc. Please provide any suggestions or feedback on these considerations, or additional considerations for measuring uncertainty?

6. We have received mixed feedback from scientific advisors as to whether or not any full stock assessment should be considered as valid (i.e. low uncertainty), with “high uncertainty” reserved for situations that lack stock assessments but may have other information such as FAO status available. What is your opinion? If you do not believe all stock assessments are low uncertainty please share any thoughts on how to rate the quality of stock assessments based on considerations such as model type, validity of and sensitivity to model inputs, confidence intervals of model outputs, etc.

In New Zealand, we basically have 3 categories (based on the Research and Science Information Standard for New Zealand Fisheries, published in 2011 by the NZ Ministry of Fisheries). Our criteria for each have been refined over time, and the way they are used now is:

1 – High Quality: applies to by far the majority of accepted stock assessments, assuming those assessments go through a rigorous review process (as they all do here)
2 – Medium or Mixed Quality: applies to a relatively small number of stock assessments, where the relevant peer review process was ambivalent about accepting the stock assessment and ended up putting a large number of caveats (more than simply “the assessment is uncertain” – they all are) on its acceptance
3 – Low quality: assessments that may have been attempted, but were rejected and therefore should not be used for management purposes

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
I can provide more detail on this if needed, but essentially if an assessment is accepted in any of the processes in place in the US and most other developed countries, as well as RFMOs etc, then in virtually all cases, it should be afforded the highest possible credibility.

7. Do you have any feedback on the proposal to eliminate the “very high concern” category?

I understand your rationale, but I have a major issue with lumping something that is simply below a limit, with something that is endangered. To me, they’re two widely different reference points.

8. Do you have any feedback on the proposal to use trend data to distinguish between stocks that are rebuilding, versus those that are below target levels and declining?

This would be a useful distinction.

9. If you agree with using trend data as described above, do you have any suggested guidance for determining a declining trend (e.g., time period <5 or more years, unless the decline has been particularly marked for a shorter recent period; I suggest NOT using generation time, else for a species like orange roughy you’ll end up having to cover a period of 30 + years and would this really be what you want? The 5 or more years is meant to encompass the entire period of decline, but I don’t think you need to specify the starting point for this>, whether decline must be monotonic <no>, what method to use for determining if it is statistically significant <regression – linear probably OK>, threshold rate of decline (steepness or slope) etc. <statistically significant is probably adequate>?)

10. Do you believe that it would be appropriate to score highly vulnerable species with weak evidence that they are not overfished as a “moderate concern”, rather than as a “low concern” (as lower vulnerability species would score) or “high concern” (as high vulnerability species currently are scored in cases where there are no clear data on abundance relative to reference points)?

Any other comments

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
Step 1: If species is of unknown abundance, assess its vulnerability. If species is of known abundance, vulnerability does not need to be assessed, and you can continue to Step 2.

1a: If a FishBase “vulnerability” score is available, use this score to continue as follows: Note: The FishBase vulnerability score is derived from Cheung et al. (2005) and is found at www.fishbase.org on the species’ page.

<table>
<thead>
<tr>
<th>FishBase vulnerability score</th>
<th>Corresponding Seafood Watch inherent vulnerability category</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>0–55</td>
<td>Low to moderate inherent vulnerability</td>
<td>Continue to Step 2.</td>
</tr>
<tr>
<td>56–100</td>
<td>Inherent vulnerability may be high</td>
<td>Continue to Step 1b.</td>
</tr>
<tr>
<td>No fishbase score</td>
<td>Inherent vulnerability may be high</td>
<td>Continue to Step 1b.</td>
</tr>
</tbody>
</table>

1b: For species that have a “high” vulnerability classification under fishbase, or no fishbase score, continue with the PSA approach below (adopted from Field et al. 2010) to classify its vulnerability.

Assign a score for each productivity attribute based on the table below. Scores will be 1, 2 or 3 for each attribute you select (if an attribute falls in between categories, intermediate scores (e.g. 2.5) may be used if well justified). Once all scores are selected, average the values to arrive at an overall vulnerability score (from 1–3). If any attribute is unknown or any value falls into an NA category (for moderate to high fecundity), that attribute is omitted from the average.

<table>
<thead>

Assign a Seafood Watch inherent vulnerability category of high, medium or low based on the overall inherent vulnerability value calculated above (the average of all attribute scores):

<table>
<thead>
<tr>
<th>Overall inherent vulnerability score from analysis</th>
<th>Corresponding Seafood Watch inherent vulnerability category</th>
</tr>
</thead>
<tbody>
<tr>
<td>Finfish</td>
<td>Invertebrates</td>
</tr>
<tr>
<td>2.44-3</td>
<td>2.46-3</td>
</tr>
<tr>
<td>1.80-2.43</td>
<td>1.85-2.45</td>
</tr>
<tr>
<td>1-1.79</td>
<td>1-1.84</td>
</tr>
</tbody>
</table>

Step 2: Score according to chart below. If species is of unknown abundance, use the vulnerability category calculated above.

<table>
<thead>
<tr>
<th>Conservation Concern</th>
<th>Description</th>
<th>Score</th>
</tr>
</thead>
<tbody>
<tr>
<td>Very Low</td>
<td>There is a reliable, credible (actually either word is OK) quantitative stock assessment, and biomass is estimated to be above or fluctuating around an appropriate target reference point, with no low uncertainty scientific controversy around that estimate, or Stock is at or very near its historic high or virgin biomass, or Species is non-native</td>
<td>5</td>
</tr>
<tr>
<td>Low</td>
<td>Stock is classified as not overfished but quantitative stock assessment is lacking, or Biomass is above the limit reference point but may be below a target reference point, and there is not a clear significant declining trend over [1]</td>
<td>4</td>
</tr>
</tbody>
</table>

Comment [pmn1]: Uncertainty isn’t what’s important – it’s bias that matters. If the assessment has been deemed to be credible / reliable by an appropriate peer review process, then additional consideration of uncertainty should not be needed.

Factor 1.3  Fishing Mortality

Public Comments Guidance

Overview – Factor 1.3 assessing whether fishing mortality for each species caught in the fishery is at an appropriate level (defined as at or below maximum sustainable yield, or an equivalent proxy). Because these same criteria are used to assess not only targeted species, but also bycatch species (under Criterion 2.3), it is necessary to provide guidance even for species that may be a relatively minor component of the catch and also are impacted by other fisheries. We distinguish between whether or not the fishery under assessment is a “substantial contributor” (which includes all target fisheries, as well as those that are one of the main contributors to fishing mortality experienced by a species; see glossary definition).

In addition to providing separate tables for assessing species depending on whether or not the fishery is a “substantial contributor” to mortality, the current criteria also integrate information on whether the stock is depleted, and management is in place. One goal of this proposal is to streamline this factor by focusing solely on fishing mortality. In addition, we are proposing to combine the “low” and “very low” concern in order to further simplification assessment of this factor.

Specific Proposed Changes:

1. Simplification of the fishing mortality table – Depleted status and whether management is in place when overfishing is occurring are accounted for in other criteria (1.2 and 3.1 respectively). Including those criteria here double-counts these issues and makes this factor unnecessarily complex. We have removed the language regarding these issues in this proposal below. We have checked that these considerations are adequately addressed in factors 1.2 and 3.1. For example, a fishery that has catch of a depleted species, experiencing overfishing, without sufficient management will get a “poor” in management criterion 3.1 which functions as a “critical” (i.e. determines an overall Avoid ranking); therefore, the separate critical score here is not needed. See the separate comment box on Scoring of Criterion 1 for examples of how these fisheries would score under the current and proposed new criteria.

Combining low and very low concern categories – Currently, the probability that overfishing is not occurring is used to distinguish “very low concern” from “low concern”. In practice, this information is often not available and it can be difficult to distinguish between “low” and “very low” concern. When they are distinguished, “low concern” species often end up scored too harshly. These species are still considered to be at a level where fishing mortality isn’t threatening the population, yet because they receive a decreased score for Factor 1.3, they may receive a low yellow or even a red score when the species is endangered or overfished (this is primarily a concern for fisheries that have a low, but not negligible, bycatch of overfished or endangered species, which is not adversely impacting that species but still greatly lowers the overall score for the fishery). Combining the categories so that all species with fishing mortality at or below a sustainable level (i.e. $F_{MSY}$ or equivalent) get full credit would help rectify this scoring concern as well as simplify assessments. See the separate comment box on Scoring of...
Criterion 1 for examples of how fisheries would score under the current and proposed new criteria.

Guidance for alternative reference points – Our current criteria are based on MSY-based reference points, and there is guidance in the appendices that reference points that are not as conservative as $F_{MSY}$ should not be considered equivalent. However, we felt this guidance needed to be more clearly stated in the criteria table itself to provide more consistency in the common situation that other reference points are used. We have proposed adding language to the “moderate concern” category to account for the case where $F$ is below a reference point, but that reference point is known to be less precautionary than $F_{MSY}$. In this case, whether fishing mortality is at a sustainable level must be considered unknown.

Feedback – please provide comments on the proposed changes, and any other comments on this factor, in the box below.

Questions for Public Comment

1. Please provide any thoughts on the simplification of Factor 1.3 by removing references to the abundance status and management of a species:

   I agree wholeheartedly! Keep it simple. In some senses, fishing mortality is a more important indicator than biomass levels given that if fishing mortality is sufficiently low then, all else being equal, stock status should always be favorable except perhaps during periods of poor environmental conditions. Even then, if $F$ is set at an appropriate level, the stock should ultimately rebuild to the corresponding average $B$.

2. Please provide any feedback on the proposal to combine the “low concern” and “very low concern” categories:

   See comments in the text.

Any Other Comments

In the situation of overfishing on an already overfished stock, it is clear that the only category that is appropriate is “Avoid”. You might want to consider applying an extra penalty for this situation by subtracting some amount of points from the overall score.

Goal: Fishing mortality is appropriate for current state of the stock.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
NOTE: Ratings are based on fishing mortality or exploitation rate, e.g., $F/F_{MSY}$. For the purposes of this table, a stock is deemed “not depleted” if rated as Very Low to Moderate Conservation Concern under 1.2; and is deemed “depleted” if rated as High to Very High Conservation Concern under 1.2. When determining whether a fishery is a substantial contributor and/or whether fishing mortality is at or below a sustainable level, err on the side of caution when there is uncertainty. For further guidance, see Appendix 1 (guidance on evaluating fishing mortality).

For Target Species or When Fishery is a substantial contributor to Mortality (include cases where fishery is one of many fisheries that equally contribute to overall mortality)

<table>

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
### Low Concern
- Fishery contribution to mortality may not be negligible, or but does not adversely affect population, **OR**
- F and/or fishery contribution is unknown, but population is not depleted and susceptibility (see Appendix 2) to fishery is low, **OR**
- Meets "Low concern" in table above.

### Moderate Concern
Fishery contribution F is unknown, but population may be depleted (and if so, management is in place) or susceptibility to fishery is moderate to high (see Appendix 2).

### High Concern
Cumulative overfishing is occurring, fishery contribution is unknown, and susceptibility to fishery is moderate to high (see Appendix 2) but population is depleted and no reasonable management to curtail overfishing is in place.

**Feedback:** Please provide any feedback on these scoring examples in the box below.

**Comments:**

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Score = geometric mean (Factors 1.2, 1.3). Factor 1.1 is not included in the calculation; instead it modifies the score of Factor 1.2 in some circumstances (See Factor 1.2 table for more information).

Rating is based on the Score as follows:
- >3.2 = Green
- >2.2 and <=3.2 = Yellow
- <=2.2 = Red

Rating is Critical if Factor 1.3 is Critical.

**Criterion 2 – Impacts on Other Species**

**Guiding principles**

*The fishery minimizes bycatch.* Seafood Watch® defines bycatch as all fisheries-related mortality or injury other than the retained catch. Examples include discards, endangered or threatened species catch, pre-catch mortality and ghost fishing. All discards, including those released alive, are considered bycatch unless there is valid scientific evidence of high post-release survival and there is no documented evidence of negative impacts at the population level.

*Fishing mortality does not threaten populations or impede the ecological role of any marine life.* Fishing mortality should be appropriate given each impacted species’ abundance and productivity, accounting for scientific uncertainty, management uncertainty and non-fishery impacts such as habitat degradation.

**Assessment instructions**

### Public Comment Guidance - Criterion 2 Instructions

**Overview** – Criterion 2 is assessed using the same criteria as Criterion 1, but is applied to bycatch and other main species that are caught together in the fishery with the species under assessment (but see specific guidelines for marine mammals, and for cases where bycatch species are unknown). The most challenging aspect of assessing Criterion 2 is determining which species need to be included for assessment. All “main species” are currently required to be fully assessed. This can be a very intensive effort, and the score for Criterion 2 is determined solely by the “worst case” species.

**Specific Proposals** – Though we do not have specific proposals for defining “main species” yet, we intend that a focus of the criteria review will be revisiting the definition of “main species” to determine a better filter for which species need to be assessed (specifically, one that is easier to assess even in data-limited situations), and one which would streamline assessments by helping analysts to assess only the key species that are likely to limit the score for Criterion 2 (without running the risk of overlooking a potential limiting species).

**Feedback** – at this time we are seeking all comments and suggestions for how to fine-tune this approach. Please provide comments below.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
The Criterion 2 score for the stock for which you want a recommendation is the lowest score of all the other main species caught with it, multiplied by the discard rate. A species is included in the assessment as a main species if:

- The catch of the species in the fishery under assessment composes >5% of that fishery’s catch, or
- The species is >1% of that fishery’s catch and the fishery causes >5% of the species’ total mortality across all fisheries, or
- The species is <1% of that fishery’s catch and the fishery causes >20% of species’ total mortality across all fisheries, or
- The species is overfished, depleted, a stock of concern, endangered, threatened, IUCN Near Threatened, US MMPA strategic species, and/or subject to overfishing and the fishery causes >1% of species’ total mortality across all fisheries.
- If there are no other “main species” (based on the above guidance) besides the one assessed under criterion 1, but the total catch of other discarded and retained species is >5% (i.e. catch of criterion 1 species is <95% of total), assess the top 3 species by volume of catch (if there are only 1-2 other species caught, assess those species).

In some cases, bycatch or retained species in the fishery are not known. If species are unknown, Appendix 3 should be used to aid scoring. If some bycatch or retained species are known but information is incomplete (e.g., some or all retained species are recorded but bycatch species are not), assess each known species following guidance for “known species” and assess the fishery following guidance for “unknown species” under each Factor. Scoring for this criterion is based on the worst case, so the lowest of these scores will be used.

If there is no bycatch and no other species landed, the fishery receives a score of five for this criterion, the remaining questions in Criterion 2 can be skipped, and the assessor can continue with Criterion 3.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
Factor 2.1  Inherent Vulnerability

Public Comment Guidance: This factor is based on Factor 1.1, with additional guidance provided for cases where there is bycatch of unknown species. As we are proposing to integrate Factor 1.1 into Factor 1.2, the same proposal applies here (to integrate Factor 2.1 into Factor 2.2).

Feedback – please provide any comments specific to Factor 2.1 (based on text below) here. If you have comments on the suggestions for Factor 1.1 or for integrating Factor 1.1/2.1 into Factor 2.1/2.2 as described in the Factor 1.1 section, please comment under Factor 1.1.

Comments

Goal: Ensure fishing mortality and other management measures are appropriate for the inherent vulnerability of all bycatch stock(s).

Known species

Follow the assessment for Factor 1.1 above (the Factors for Inherent Vulnerability, Stock Status and Fishing Mortality are identical for all main species caught in the fishery, whether target, other retained or discarded).

Unknown species

Where the catch composition is not completely known, use Appendix 3 to identify those taxa that are most likely to interact substantially with the fishing gear, defined as taxa scoring a 3.5 or below. The numbers in the unknown bycatch matrix will be used extensively for scoring Criterion 2.3.

Vulnerability is assigned to the taxa that are identified as interacting with the fishery as follows:

High = marine mammals, turtles, sharks, seabirds, deepwater and shallow biogenic habitat (seagrass beds, coral, sponges, etc.). Moderate = invertebrates and fish.

Factor 2.2  Abundance

Public Comment Guidance: This factor is based on Factor 1.2, with additional guidance for cases where there is bycatch of unknown species.

Feedback – please provide any comments specific to Factor 2.2 (based on text below) here. If you have comments on the suggestions for Factor 1.2, please comment under Factor 1.2.

Comments

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
**Goal:** Stock abundance and size structure of all main bycatch species/stocks is maintained at a level that does not impair recruitment or productivity.

**Known species**

Follow the assessment for Factor 1.2 above (the Factors for Inherent Vulnerability, Stock Status and Fishing Mortality are identical for all main species caught in the fishery, whether target, other retained or discarded).

**Unknown species**

If bycatch species and/or other retained species are unknown, use Appendix 3, the unknown bycatch matrix, and additional bycatch guidance (in Appendix 3) to determine the types of taxa that are likely to interact with the fishery based on gear type and location. Factor 2.2 is scored as “moderate concern” for each taxon listed in Appendix 3 for this type of fishery with a score of 3.5 or below unless the taxon is comprised largely of species that are either of high vulnerability as scored in Factor 2.1, or overfished, endangered or threatened within the range of the fishery (e.g., sea turtles, seabirds, marine mammals and sharks); in these cases, it is scored as “high concern.” Species scoring a 4 or above do not need to be addressed.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Public Comment Guidance for Factor 2.3

Overview – Generally, Criterion 2.3 follows the structure of Criterion 1.3, and the same changes proposed there will be applicable here as well. In addition, there is special guidance for marine mammals which have quantitative information and classifications when caught in US fisheries (managed under the Marine Mammal Protection Act). We are proposing one minor change to this special guidance.

Specific Proposal – SFW has determined that the guidance here is overly harsh in cases where total mortality for a species does not exceed its Potential Biological Removal (PBR). In these cases, a fishery may be scored “moderate” in some instances; however, in all cases if PBR is not exceeded by cumulative fishing mortality, then the mortality is at a sustainable level, and thus a “low concern” would be most appropriate. Here we propose an edit such that all species that are experiencing cumulative fishing mortality levels below PBR are scored as a “low concern” for Factor 2.3 for all fisheries that interact with them.

We also propose removing references to the “very low concern” category, as we are proposing removing that category from 2.3 altogether.

Feedback – Please provide comments on this proposed change below:

Question
Please provide any comments on the proposal to refine the guidance for marine mammals, as described above and shown in redlining below:

Any Other Comments on 2.3:

Goal: Fishing mortality is appropriate for the current state of all main bycatch species/stocks.

Known species

Follow the assessment for Factor 1.3 above (the Factors for Inherent Vulnerability, Stock Status and Fishing Mortality are identical for all main species caught in the fishery, whether target, other retained or discarded).

Additional guidance for scoring of marine mammals caught in US fisheries is given below (due to the availability of data on potential biological removal (PBR) and fishing mortality rates on all bycaught marine mammals, available in marine mammal stock assessments and List of Fisheries reports, see http://www.nmfs.noaa.gov/pr/interactions/lof/)

If PBR or fishery mortality relative to PBR is not known, score conservatively given what is known (e.g., fishery and/or species classification) or score as “moderate”. Example: if it is unknown but fishery is classified as Category II and species is not strategic, score as “low”.

**Unknown species**

*If bycatch and/or other retained species are unknown, use Appendix 3, the unknown bycatch matrix, and additional bycatch guidance (in Appendix 3) to determine the types of taxa that are likely to interact with the fishery based on gear type and location. Each score from Appendix 3 has a corresponding fishing mortality conservation concern (below).*

*Appendix 3, the unknown bycatch matrix and additional guidance for unknown bycatch species should ONLY be used as a general guide to help rate bycatch potential (for Factor 2.3, mortality caused by the fishery) when no data on the composition of bycatch are available. In these cases, Appendix 3 provides guidance based on gear-type and its potential to interact with species other than the target fishery, as reported in the scientific literature. When assigning a conservation concern for unknown bycatch, other factors to consider before using the unknown bycatch matrix include: geographic range of the fishery, degree of overlap, if any (with foraging areas, breeding grounds, etc.) there is between fishing and potential bycatch species, fishing depth, whether the fishery is operating in coastal (some coastal areas may have a greater impacts on some species) or open-ocean systems, whether the fishery operates seasonally and coincides with breeding season, and other concerns based on fishing region and the conservation concern for the potential bycatch species. Species with scores above 3.5 from the unknown bycatch matrix do not need to be addressed.*

Factor 2.4  Modifying Factor: Discards and Bait Use

Public Comment Guidance: Another goal of the criteria review, with respect to Criterion 2, will be to collaborate with the aquaculture team regarding the scoring for discard rates and bait use (Factor 2.4) to ensure that there is consistency with the scoring of feed use in aquaculture reports. In addition, because bait use is considered in 2.4 but is rarely quantified, we aim to provide default scores for bait use, based on literature review, for a variety of fishery types (target species and gear). We will provide an opportunity to override these default scores if data specific to the fishery can be provided.

Please provide any comments on these ideas or the current text of Factor 2.4 below.

Goal: Fishery optimizes the utilization of marine resources by minimizing post-harvest loss and by efficiently using marine resources as bait.

Instructions: This weighting factor is addressed once for each fishery under assessment. Ascertain whether bycatch species are known or not. Both bait and dead discards are considered relative to total landings. This ratio refers to the total dead discards and/or bait use relative to total landings of all species caught in the fishery. The discard mortality rate is generally assumed to be 100% (i.e., all discards count as dead discards). Exceptions include cases where research has demonstrated high post-release survival, including invertebrates caught in pots and traps. Research that demonstrates high post-release survival for the same or similar species caught with the same or comparable gear types may qualify as showing high post-release survival. When discard mortality rates are known, multiply these rates by the amount of discards for the relevant species to determine the amount of dead discards. If the bycatch:landings ratio and/or bait use are unknown, refer to average bycatch rates for similar fisheries (based on gear type, target species and/or location) as given in review papers (e.g., Kelleher 2005 and Alverson et al. 1994). Bait use, if unknown, need only be addressed in cases where it is likely to be substantial relative to landings (e.g., lobster pot fishery). Err on the side of caution when there is no information.

Criterion 2 Score and Rating

Criterion 2 Score for the stock for which you want a recommendation = Subscore * Discard Rate (Factor 2.4).

- Subscore = lowest score of all other assessed species caught.
  - Score for each species = geometric mean (Factors 2.2, 2.3). Factor 2.1 is not included in the calculation; instead it modifies the score for Factor 2.2 in some circumstances (See Factor 2.2 table for more information).

Rating is based on the lowest Subscore as follows:
- >3.2 = Green
- >2.2 and <=3.2 = Yellow
- <=2.2 = Red

Rating is Critical if Factor 2.3 is Critical.

Criterion 3 – Management Effectiveness

Public Comment Guidance

Overview – Criterion 3 (Management Effectiveness) deals with the effectiveness of the harvest strategy, implementation, enforcement and monitoring to control fishing pressure on the managed species, as well as effectiveness of bycatch management. This criterion is composed of two factors – Harvest Strategy (3.1) and Bycatch Management Strategy (3.2), each of which is composed of numerous subfactors.

Goals for Criteria Review – While we don’t have specific proposals at this time, a goal of the criteria review is to streamline this criterion and improve its ability to distinguish better management systems. Criticisms of the current system are that it is not effectively highlighting the nuances of better management (most management systems score “moderately effective”), and is needlessly complicated, as it involves scoring numerous subfactors that rarely affect the score.

Feedback – We are interested in any and all feedback on this criterion. We have outlined specific questions for consideration under each of Factor 3.1 and Factor 3.2. In addition, please provide general comments on this criterion below.

Comments:

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Guiding principles

The fishery is managed to sustain the long-term productivity of all impacted species. Management should be appropriate (see Appendix 4 for more guidance) for the inherent vulnerability of affected marine life and should incorporate data sufficient to assess the affected species and manage fishing mortality to ensure little risk of depletion. Measures should be implemented and enforced to ensure that fishery mortality does not threaten the long-term productivity or ecological role of any species in the future.

Assessment instructions

Assess Factors 3.1 and 3.2 once for each fishery.

Factor 3.1  Harvest Strategy

Public Comment Guidance

Overview – Criterion 3.1 addresses the effectiveness of the harvest strategy for managed species, including the following subfactors: management strategy and implementation, recovery of species of concern, research and monitoring, record of following scientific advice, track record, enforcement, and stakeholder involvement.

We are seeking to streamline this criterion (ideally reducing the number of subfactors) and improve its ability to distinguish better management strategies.

Specific Proposals – We do not yet have specific proposals to streamline this category. We are proposing to eliminate the “critical” category for Factor 3.1 (see redline and strikethrough below), as it is unnecessary because any fisheries scoring a “very high concern” (1) on Factor 3.1 are automatically rated Avoid; therefore the “very high concern” is already operating as a critical factor. In addition, we propose some specific language for the “very high concern” category that would ensure that fisheries that catch species that are overfished with overfishing occurring, and do not have management in place to end overfishing and rebuild the stocks, are scored in this category. This addition is considered to be equivalent to the language previously in Factor 1.3 that scored fisheries as “Critical” in these cases.

Feedback – Please provide feedback on specific questions below.

Comments:

Questions:

1. Please consider the subfactors included for each factor below. Which of these seem most important? Should any be weighted more heavily in the final scoring?

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
2. Which, if any, may be unnecessary to score at all? Should any subfactors be combined?

3. Are there any additional considerations you would like to propose including in this criterion (this may include new subfactors, or changing the descriptions of the categories for each subfactor to include new considerations?

4. Do you have any thoughts on whether it would be more appropriate to have more than three scoring categories (currently highly effective, moderately effective or ineffective) for each subfactor, in order to provide more nuanced differentiation of management effectiveness?

5. Please provide any feedback on eliminating the “critical” concern under 3.1 (keeping in mind that all fisheries rating “very high concern” for 3.1 are already scored “Avoid”.

6. Other comments:

Goal: Management strategy has a high chance of preventing declines in stock productivity by taking into account the level of uncertainty, other impacts on the stock, and the potential for increased pressure in the future. See Appendix 4 for more guidance.

Instructions
Step 1: Assign a rating for each of the seven management subfactors using the table below:

<table>
<thead>
<tr>
<th>Management strategy and implementation</th>
<th>Highly effective</th>
<th>Moderately effective</th>
<th>Ineffective</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fishery has highly appropriate strategy and goals, and there is evidence (scientific or other rigorous source) that the strategy is being implemented successfully</td>
<td>Some effective management (see Appendix 4) is in place, but there is a need for increased precaution (e.g., stronger reductions)</td>
<td>Management strategy is insufficiently precautionary to protect populations or strategies have not been implemented</td>
<td></td>
</tr>
</tbody>
</table>

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
For non-native species, management policy allows for prevention of further spread and reductions in biomass over time or suppression of biomass to low levels (e.g. below Bmsy), or includes mechanisms to allow for recovery of species impacted by the non-native; and management is not exacerbating concern with the non-native, e.g. through stocking or seeding. Some examples of highly effective management are included in Appendix 4.

In TAC when biomass declines, quicker reaction to changes in populations, etc.), or management strategy is moderately successful at achieving goals.

For non-native species, increases in stock size and further spread are prevented through harvesting or other management measures; if any stocking or seeding occurs, species is already established and ongoing stocking/seeding activity has been demonstrated not to contribute to growth or spread of non-native population.

For non-native species, there are known or likely negative impacts on the ecosystem, fishery is maintained in part through stocking/seeding/etc., and/or stock size or further spread are not controlled by harvesting or other strategies.

### Recovery of species of concern

If overfished, depleted, endangered or threatened species are targeted and/or retained, management has a rebuilding or recovery strategy in place with a high likelihood of success in an appropriate timeframe, and best management practices (Appendix 4) are in use to minimize mortality of these species to the greatest extent possible, and harvest control rules are in place that will allow for rebuilding.

OR

There are currently no overfished, depleted, endangered or threatened species targeted or retained in the fishery.

If overfished, depleted, endangered or threatened species are targeted and/or retained, management has a rebuilding or recovery strategy in place whose eventual success is probable, or best management practices to minimize mortality of "stocks of concern" are in use where needed and are believed to be effective.

OR

Fishery is not a substantial contributor to mortality of the species, management lacks an adequate rebuilding or recovery strategy and/or effective practices designed to limit mortality of these species.

### Scientific research

**The management process**

Some collection of data

No data or very little data available.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
| and monitoring | uses an independent and up-to-date scientific stock assessment or analysis, or other appropriate method that seeks knowledge related to stock status, **and** this assessment is conducted regularly and is complete and robust, which may include both fishery-independent and appropriate fishery-dependent data **and** Abundance and geographic range of any non-native target species are monitored | related to stock abundance and health is collected, but data may be insufficient (or too uncertain) to maintain stock | minimal data are collected |
| Management record of following scientific advice | Management nearly always follows scientific advice (e.g., does not have a track record of exceeding advised TACs or otherwise disregarding scientific advice) | Management only sometimes follows scientific advice (e.g., only sets TACs at or below the recommended level half of the time) | Management has a track record of regularly exceeding recommended TACs, or otherwise not complying with scientific advice |
| Enforcement of management regulations | Regulations and agreed voluntary arrangements are regularly enforced and independently verified, including VMS, logbook reports, dockside monitoring and other similar measures appropriate to the fishery | Enforcement and/or monitoring are in place to ensure goals are successfully met, although effectiveness of enforcement/monitoring may be uncertain (e.g., regulations are enforced by fishing industry or by voluntary/honor system, but without regular independent scrutiny) | Enforcement and/or monitoring is lacking or believed to be inadequate, or compliance is known to be poor |
| Management track record | Measures enacted by management have resulted in the long-term maintenance of ecosystem integrity, including maintaining stock abundance at appropriate levels, given its role in the ecosystem and whether it is native to the ecosystem | Measures enacted by management have not been in place long enough to evaluate, or the track record is uncertain | Management measures currently in place have resulted in native stock declines and/or failed to allow depleted native stocks to recover; or have helped to support the establishment and/or spread of a non-native species |

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
The management process is transparent and includes stakeholder input. There is limited transparency, stakeholder input or consultation. Stakeholders are not included in decision-making and decisions are not made transparently.

**Step 2:** Assign a rating and a score for the fishery’s management of impacts on retained stocks (Criterion 3.1 score) based on the seven subfactors rated above.

<table>
<thead>
<tr>

</thead>
</table>

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Factor 3.2  Bycatch Management Strategy

Public Comment Guidance

Overview – Criterion 3.1 addresses the effectiveness of the harvest strategy for managed species, including the following subfactors: management strategy and implementation, recovery of species of concern, research and monitoring, record of following scientific advice, track record, enforcement, and stakeholder involvement.

We are seeking to streamline this criterion (ideally reducing the number of subfactors) and improve its ability to distinguish better management strategies.

Specific Proposal – We do not yet have specific proposals to streamline this category. We are proposing to eliminate the “critical” category for Factor 3.2 (see redline and strikethrough below), as it is unnecessary because any fisheries scoring a “very high concern” (1) on Factor 3.2 are automatically rated Avoid; therefore the “very high concern” is already operating as a critical factor.

In addition to streamlining, we are considering one major change to this factor. Currently, fisheries that are highly selective (e.g. harpoon, etc.) are scored N/A for this factor as bycatch management is unneeded. When 3.2 is scored as N/A, the entire score for management (Criterion 3) is based on the score of 3.1. This has the unintended effect of producing higher scores in some cases for less selective fisheries. We are proposing to score highly selective fisheries as “very low concern” for bycatch management, rather than N/A.

Feedback – Please provide feedback on specific questions below.

Comments:

Questions:

1. Do you agree or disagree with the proposal to score highly selective fisheries as “very low concern” for bycatch management? Why?

2. Please consider the subfactors included for each factor below. Which of these seem most important? Should any be weighted more heavily in the final scoring?

3. Which, if any, may be unnecessary to score at all? Should any subfactors be combined?

4. Are there any additional considerations you would like to propose including in this criterion (this

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
may include new subfactors, or changing the descriptions of the categories for each subfactor to include new considerations?

5. Do you have any thoughts on whether it would be more appropriate to have more than three scoring categories (currently highly effective, moderately effective or ineffective) for each subfactor, in order to provide more nuanced differentiation of management effectiveness?

6. Please provide any feedback on eliminating the “critical” concern under 3.2 (keeping in mind that all fisheries rating “very high concern” for 3.2 are already scored “Avoid”.

7. Other comments:

Goal: 

Management strategy prevents negative population impacts on bycatch species, particularly species of concern.

If the fishery has very low or no bycatch (due to highly selective gear, seasonal effort or other), score Factor 3.2 as very low concern (score of 5). as N/A for bycatch management and the management score will be based solely on Factor 3.1.

Instructions

Step 1: Assign a rating for each of the four management subfactors using the table below:

<table>
<thead>
<tr>
<th>Management strategy and implementation</th>
<th>Highly effective</th>
<th>Moderately effective</th>
<th>Ineffective</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Fishery has highly effective or precautionary strategy and goals designed to understand and minimize the impacts of the fishery on bycatch species, and there is evidence that the strategy is being implemented successfully (e.g., there is a well-known track record of consistently setting conservative bycatch limits</td>
<td>Strategy or implementation effectiveness is under debate or uncertain (e.g., bycatch limits are imposed based on assumptions, but limits are disputed or unsure, or bycatch reduction techniques are in place but insufficient given the potential impacts of the fishery (e.g., a fishery that is heavily or fully exploited with no data collection or monitoring</td>
<td>Management measures such as bycatch limits or bycatch reduction techniques (Appendix 5) are in place but insufficient given the potential impacts of the fishery (e.g., a fishery that is heavily or fully exploited with no data collection or monitoring</td>
</tr>
</tbody>
</table>

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
based on quality information and advice about bycatch, or bycatch is minimized to the greatest extent possible, especially for vulnerable species such as sharks, seabirds, turtles, marine mammals and some fish through mitigation measures (see Appendix 5 for guidance), area closures or other bycatch reduction techniques (Appendix 5) that have been shown to be highly effective are used but are of unknown or uncertain effectiveness, or management has not been in place long enough to evaluate its effectiveness or is unknown to ensure the health of bycatch populations), or No management if bycatch concerns are possible (based on region and gear type) but remain unknown

<table>
<thead>
<tr>
<th>Scientific research and monitoring</th>
<th>Collection of observer or effective video monitoring data exists, but coverage or analysis is limited</th>
<th>No regular collection or analysis of data, or no significant scientific research support</th>
</tr>
</thead>
<tbody>
<tr>

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Criterion 3 Score and Rating

Score = geometric mean (Factors 3.1, 3.2)

Rating is based on the Score as follows:
- **Green** if >3.2
- **Yellow** if >2.2 and <=3.2 and neither Harvest Strategy (Factor 3.1) nor Bycatch Management Strategy (Factor 3.2) are Very High Concern or Critical
- **Red** if <=2.2 or either the Harvest Strategy (Factor 3.1) or Bycatch Management Strategy (Factor 3.2) is Very High Concern

Rating is **Critical** if either or both of Harvest Strategy (Factor 3.1) and Bycatch Management Strategy (Factor 3.2) are Critical.

### Criterion 4 – Impacts on the Habitat and Ecosystem

**Public Comment Guidance for Criterion 4**

**Overview** – Criterion 4 includes assessment of impacts on the seafloor habitat, and other indirect ecosystem impacts with a focus on food web/trophic impacts. Factor 4.1 scores a fishery’s likely impact on the seafloor habitat based on gear type and substrate, while 4.2 allows the fishery to improve on that score due to mitigation efforts such as gear modification and spatial closures. Factor 4.3 focuses on food web impacts and the use of ecosystem-based management to avoid negative trophic impacts, as well as other ecological impacts not covered elsewhere (e.g. due to hatcheries or FADs).

**Specific Proposals** – 1) We are proposing a minor restructuring of Factors 4.1 and 4.2. As is, these are scored separately and each is assigned a category, but the seafloor impact is determined by the sum of the two. To emphasize that these two factors combine to create the score for impact on the habitat, we propose to rename these as Factor 4.1a and 4.1b and to assign a category (based on corresponding numerical scores) only for Factor 4.1 as a whole (the sum of 4.1a and 4.1b). Calculation of scoring would not change, therefore this would not lead to any substantive changes in ratings or reports.

2) We are proposing substantial changes to Factor 4.3, primarily to incorporate the specific guidance from the Lenfest Task Force on Forage Species. Please see the box under Factor 4.3 for more details and questions.

3) We are considering moving Factor 4.3 into a new, separate criterion, as it is really a separate impact from habitat effects. This would have potentially significant effects on rankings, especially due to the decision rule that one red criterion results in a Good Alternative at best and two red criteria result in an Avoid ranking. Currently, averaging factors 4.1+4.2 and 4.3 often results in a yellow for Criterion 4 overall, whereas if these two factors were assessed separately, in many cases one of them would be red. Therefore, this change would likely result in downgrades for some fisheries.

**Feedback** – Please see questions below and provide any general feedback or comments on the proposed structural changes.

Please see Factor 4.3 for more details on the proposed changes for that factor, and please provide relevant comments in the box under 4.3.

**Questions:**

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
1. Do you believe that Factor 4.3 (Ecosystem-Based Management, with a focus on Food Web) should be combined with habitat impacts in one criterion as it is currently, or should be a stand-alone criterion (or other suggestion)?

Comments:

Guiding principles

The fishery is conducted such that impacts on the seafloor are minimized and the ecological and functional roles of seafloor habitats are maintained.

Fishing activities should not seriously reduce ecosystem services provided by any fished species or result in harmful changes such as trophic cascades, phase shifts or reduction of genetic diversity.

Assessment instructions

Address Factor 4.1–4.2 for all fishing gears separately. Assess Factor 4.3 once per fishery.

**Factor 4.1a Impact of Fishing Gear on the Habitat/Substrate**

Public Comment Guidance for Factors 4.1 and 4.2

Redlining below demonstrate how we propose to combine the current Factors 4.1 and 4.2 (which would be renamed 4.1a and 4.1b). This rearrangement is for communication purposes and would not materially affect the scoring for these factors in any way.

Comments

Goal: The fishery does not adversely impact the physical structure of the seafloor or associated biological communities.

Instructions: Fishing gears that do not contact the seafloor score 5 for this criterion, and Factor 4.2 can be skipped. Use the table below to assign a score for gear impacts (Appendix 6 provides further guidance). If gear type is not listed in the table, use the score for the most similar gear type in terms of extent of bottom contact. Seafood Watch will not assess a fishery using destructive gear such as explosives or cyanide regardless of habitat type and management actions; therefore, those fishing methods are not included in the table. Where multiple habitat types are commonly encountered, and/or the habitat classification is uncertain, score conservatively according to the most sensitive plausible habitat type. See Appendix 6 for further guidance and the methods used in developing the table below.

</tr>
</tbody>
</table>

**Factor 4.2.4.1b Modifying Factor: Mitigation of Gear Impacts**

**Goal:** Damage to the seafloor is mitigated through protection of sensitive or vulnerable seafloor habitats, and limits on the spatial footprint of fishing on fishing effort.

**Instructions:** Assess Factor 4.2 only for fishing gear that contacts the bottom. Scores from Factor 4.2 can only improve the base score from 4.1. A high level of certainty is required to score a strong or moderate mitigation measure, e.g., good quality seafloor maps, VMS and/or observer coverage is required to document that spatial measures are effective and enforced. Further guidance can be found in Appendix 7.

Assess whether the fishery management’s efforts to mitigate the fishery’s impact on the benthic habitat fall into the categories strong, moderate, minimal or no effective mitigation, based on the table below. Factor 4.2 allows the habitat score to increase, based on the strength of mitigation measures, by the number of bonus points specified in the table.

| Strong mitigation | At least 50% of the representative habitat is protected from the gear type used in the fishery under assessment (see Appendix 7). or Fishing intensity is sufficiently low and limited such that it can be scientifically demonstrated that at least 50% of the representative habitat is in a recovered state, based on knowledge of the resilience of the habitat and the frequency of fishing impacts from the gear type used in the fishery under assessment (see Appendix 7), or Gear is specifically designed to reduce impacts on the seafloor and there is | +1 |

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
scientific evidence that these modifications are effective in this regard and modifications are used on the majority of vessels, or Other measures are in place that have been demonstrated to be highly effective in reducing the impact of the fishing gear, which may include an effective combination of two or more “moderate” measures described below, e.g., gear modifications + spatial protection.

<table>
<thead>
<tr>
<th>Moderate mitigation</th>

**Scoring for Factor 4.1: Impact on the Habitat**

The score for Factor 4.1 is the sum of the score for 4.1a and the score for 4.1b. The category name for 4.1 is assigned based on score ranges, as below:

<table>
<thead>
<tr>
<th>Score (Sum of 4.1 and 4.2)</th>

**Factor 4.3  Ecosystem-based Fisheries Management**

**Public Comment Guidance for Factor 4.3**

**Overview** – This factor assess any indirect ecological impacts not captured elsewhere in the criteria, but the focus is on potential trophic impacts, and the effectiveness of management in constraining fishing

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
mortality to levels that are appropriate given the species’ ecological role.

**Specific Proposals** – At the time of writing the current criteria, there was no scientific consensus on appropriate management with regard to food web impacts. Since that time, the Lenfest Forage Fish Task Force (see [http://www.oceanconservationscience.org/foragefish/](http://www.oceanconservationscience.org/foragefish/)) developed very detailed guidance for the management of forage fisheries. We aim to incorporate that scientific advice into our criteria. We hope, during the course of this consultation, to develop more guidance for ecosystem-based management of fisheries targeting species of exceptional importance to the ecosystem other than forage fish as well (e.g., top predators or foundational species).

The specific proposal is not yet developed into redline in the text below. The aim is to incorporate the detailed advice from the Lenfest report with the following scoring guidance:

- Fisheries on forage species (using Lenfest definition) must conform to all the recommendations of the Task Force in order to score green for this factor.
- Fisheries on forage species that do not meet all the recommendations, but at least incorporate a minimum biomass threshold and a fishing mortality limit at the levels recommended by the Task Force will score yellow for this factor.
- Fisheries on forage species which have a biomass threshold significantly lower or a fishing mortality threshold significantly higher than Lenfest recommends will score red for this factor.

**Feedback** – Please provide any thoughts and comments on the proposal in the box below.

**Questions:**

1. Do you agree with the proposal to use the specific guidance in the Lenfest Forage Fish Task Force report in this factor?

2. If so, do you agree with the suggested guidelines for determining green, yellow, or red scores based on the Task Force recommendations?

3. Do you have any suggestions for how to score forage fisheries for this factor?

4. Should Seafood Watch also address management of fisheries on top predators in this criterion (with scores based on requirements that are designed to maintain the ecological role of predators)? Is there sufficient information to effectively determine special guidelines for fisheries on predators?

5. Do you have any suggestions for how to score fisheries for species with other ecological roles for this factor?

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Goals: All stocks are maintained at levels that allow them to fulfill their ecological role and to maintain a functioning ecosystem and food web. Fishing activities should not seriously reduce ecosystem services provided by any retained species or result in harmful changes such as trophic cascades, phase shifts or reduction of genetic diversity. Even non-native species should be considered with respect to ecosystem impacts. If a fishery is managed in order to eradicate a non-native, the potential impacts of that strategy on native species in the ecosystem should be considered and rated below.

Instructions: Assign an ecosystem-based management score for the fishery, taking into consideration the ecosystem role of the main species in the fishery, and whether they are “species of exceptional importance.” Species of exceptional importance are native species that play a disproportionately important role relative to their biomass. These may include habitat-forming species, forage species, top predators, keystone species, ecosystem engineers, etc. A species should not be considered of “exceptional importance” unless it clearly fits in one of these categories or there is clear evidence that it plays a keystone role in the ecosystem.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
The fishery catches “exceptional species” and lacks policies to protect the ecosystem role of these species, but scientific assessment to account for these species’ ecological roles is underway, or For fisheries with hatchery supplementation, and/or use of FADs, negative ecological and/or genetic impacts from these practices are possible and management is not designed to minimize these impacts, or For fisheries on non-native species, the policies to manage the fishery and/or control the spread of the non-native species have an unknown effect on native species.

| High | The fishery catches “exceptional species” and there are no explicit efforts to incorporate ecological role into management, or For fisheries on non-native species, policies in place to manage the fishery and/or control the spread of the species have adverse effects on native species. | 2 |
| Very High | For fisheries with hatchery supplementation, and/or use of FADs, practices are in use that have been demonstrated or believed to have serious negative ecological and/or genetic impacts, or Scientifically demonstrated trophic cascades, alternate stable states, or other detrimental food web impacts are resulting from the fishery. | 1 |

**Criterion 4 Score and Rating**

Score = geometric mean (Factors 4.1+4.2, 4.3)

Rating is based on the Score as follows:
- >3.2 = Green
- >2.2 and <=3.2 = Yellow
- <=2.2 = Red

Rating cannot be Critical for Criterion 4.

**Overall Score and Final Recommendation**

**Public comment guidance.**

**Overview** – The final scoring system combines the individual criterion scores to produce a numerical final score from 0-5, but also applies decision rules based on the number of “high concerns”, i.e. “red” scoring criteria as outlined below.

**Specifics** – The following sections show how the final score and final recommendation are calculated from the individual criterion scores. It is the current philosophy of the SFW criteria that regardless of the final numerical score, if there is one red criterion (with a numerical score <=2.2), then the highest possible final recommendation is a yellow “Good Alternative”. If there

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
are two red criteria, then the overall final recommendation will be red “Avoid” regardless of the numerical score. If there is one or more “critical concerns” then the final recommendation is red “Avoid” regardless of the numerical score.

Feedback – In general the scoring system has worked, and the final recommendation is often decided by the presence of one or more red scores. The criteria are not weighted in any way at present (i.e. they all have equal weighting). This part of the criteria is critical to the appropriate final recommendation for every Seafood Watch assessment, and we welcome feedback and suggestions for improvement.

Comment

Final Score = geometric mean of the four Scores (Criterion 1, Criterion 2, Criterion 3, Criterion 4).

The overall recommendation is as follows:

- **Best Choice** = Final Score >3.2, and no Red Criteria, and no Critical scores
- **Good Alternative** = Final score >2.2, and neither Harvest Strategy (Factor 3.1) nor Bycatch Management Strategy (Factor 3.2) are Very High Concern5, and no more than one Red Criterion, and no Critical scores, and does not meet the criteria for Best Choice (above)
- **Avoid** = Final Score <=2.2, or either Harvest Strategy (Factor 3.1) or Bycatch Management Strategy (Factor 3.2) is Very High Concern5, or two or more Red Criteria, or one or more Critical scores.

---

5 Because effective management is an essential component of sustainable fisheries, Seafood Watch issues an Avoid recommendation for any fishery scored as a Very High Concern for either factor under Management (Criterion 3).

*Underlined terms have been defined in the glossary. Ctrl + Click to view.*
Adequate observer coverage:
Observer coverage required for adequate monitoring depends on the rarity of the species caught, with fisheries that interact with rare species requiring higher coverage. Similarly, species that are “clumped” instead of being evenly distributed across the ocean also require higher levels of coverage. In addition, fisheries using many different gear types and fishing methods require higher levels of coverage. Bias may also be introduced if some areas, gear and seasons of a fishery are not well sampled. For these reasons, the exact level of coverage required for a particular fishery depends on the distribution of a species within the fishery as well as its associated discard and target species (Babcock and Pikitch 2003). The analyst will need to determine what level of observer coverage is adequate for the fishery of interest; coverage of 17–20% (or as high as 50% for rare species bycatch) may be required in some cases but may not be necessary in all cases.

Appropriate reference points:
Determination of the appropriateness of reference points depends on two questions:

1) Is the goal appropriate? Appropriate biomass reference points are designed with the goal of maintaining stock biomass at or above the point where yield is maximized (target reference points; TRPs) and safely above the point where recruitment is impaired (limit reference points; LRP). Ideally, biomass reference points aim to maintain stock biomass at levels that allow the stock to fulfill its role in the ecosystem. Fishing mortality reference points should be designed with the goal of ensuring that catch does not exceed sustainable yield and has a very low likelihood of leading to depletion of the stock in the future.

2) Is the calculation of the reference points credible? There may be a concern if reference points have been lowered repeatedly or if there is scientific controversy regarding the reference points or the calculations of biomass and fishing mortality relative to reference points.

See the guidance for each type of reference point below and in Appendix 1.

Target reference point: Reference points need to be evaluated on a case-by-case basis, but in general: Biomass target reference points (TRPs) should generally not be lower than BMSY or approximately B35–B40%. TRPs below about B35% require strong scientific rationale. See Appendix 1 for more details.

Limit reference point: The point where recruitment would be impaired. Reference points need to be evaluated on a case-by-case basis, but in general: Biomass limit reference points (LRPs) should be no less than ½ BMSY, or ½ an appropriate target reference point such as B40%. LRP below about B20% or ½ BMSY require strong scientific rationale.

Spawning potential ratio/fraction of lifetime egg production (SPR/FLEP) reference point: The SPR/FLEP limit reference point should either be derived through scientific analysis to be at or above replacement %SPR for the species (the threshold level of SPR necessary for replacement) based on its productivity and S-R relationship (viz., Mace and Sissenwine 1993), or should be set at about 35–40% of LEP. An exception can be made for species with very low inherent productivity (e.g., rockfish, sharks), in which case a reference point of 50–60% of LEP is more appropriate (Mace and Sissenwine 1993, Myers et al. 1999, Clark 2002, Botsford and Parma 2005).
Bycatch:
Refers to all fisheries-related injury or mortality other than in the retained catch. Examples include discards, endangered or threatened species catch, pre-catch mortality and ghost fishing. All discards, including those released alive, are considered bycatch unless there is both valid scientific evidence of high post-release survival and no documented evidence of negative impacts at the population level.

Critically endangered:
An IUCN category for listing endangered species. A taxon is considered “critically endangered” (CE) when it faces an extremely high risk of extinction in the wild in the immediate future, as defined by any of the relevant IUCN criteria for “critically endangered” (FAO Glossary; IUCN).

Data-moderate:
Reliable estimates of MSY-related quantities are either unavailable or not useful due to life history, a weak stock-recruit relationship, high recruitment variability, etc. Reliable estimates of current stock size, life history variables and fishery parameters exist. Stock assessments include some characterization of uncertainty (Restrepo and Powers 1998; Restrepo et al. 1998).

Data-poor:
Refers to fisheries for which there are no estimates of MSY, stock size, or certain life history traits. There may be minimal or no stock assessment data, and uncertainty measurements may be qualitative only (Restrepo and Powers 1998; Restrepo et al. 1998).

Data-rich:
Refers to fisheries with reliable estimates of MSY-related quantities and current stock size. Stock assessments are sophisticated and account for uncertainty (Restrepo and Powers 1998; Restrepo et al. 1998).

Depleted:
A stock at a very low level of abundance compared to historical levels, with dramatically reduced spawning biomass and reproductive capacity. Such stocks require particularly energetic rebuilding strategies. Recovery times depend on present conditions, levels of protection and environmental conditions. May refer also to marine mammals listed as “depleted” under the Marine Mammal Protection Act (FAO Glossary). Classifications of “overfished” or “depleted” are based on assessments by the management agency and/or FAO, but analysts can use judgment to override the classification, especially where the prior assessment may be out of date (also includes IUCN listings of “near threatened”, “special concern” and “vulnerable”). Inclusion in this classification based on designations such as “stock of concern” is determined on a case-by-case basis, as such terms are not used consistently among management agencies. Stocks should be classified as “depleted” if the stock is believed to be at a low level of abundance such that reproduction is impaired or is likely to be below an appropriate limit reference point. Marine mammals classified as “depleted” under the Marine Mammal Protection Act fall into this category, if not listed as endangered or threatened. Also includes stocks most likely (>50% chance) below the level where recruitment or productivity is impaired. Note: Official IUCN listings should be overridden by more recent and/or more specific classifications, where available (e.g., NMFS stock assessment showing stock is above target levels).

Ecological role:
The natural trophic role of a stock within the ecosystem under consideration in an assessment (MSC 2010).
Effective:
Management or mitigation strategies are defined as “effective” if a) the management goal is sufficient to maintain the structure and function of affected ecosystems in the long-term, and b) there is scientific evidence that they are meeting these goals.

Effective mitigation or gear modification:
A strategy that is “effective” as defined above, either in the fishery being assessed or as demonstrated in a very similar system (See Appendix 4 and Appendix 5 for a partial list of effective mitigations; this list will be continually developed).

Endangered/threatened:
Taxa in danger of extinction and whose survival is unlikely if causal factors continue operating. Included are taxa whose numbers have been drastically reduced to a critical level or whose habitats have been so drastically impaired that they are deemed to be in immediate danger of extinction (FAO Fisheries Glossary). This classification includes taxa listed as “endangered” or “critically endangered” by IUCN or “threatened”, “endangered” or “critically endangered” by an international, national or state government body, as well as taxa listed under CITES Appendix I. This classification does not include species listed by the IUCN as “vulnerable” or “near threatened”. Marine mammals listed as “strategic” under the Marine Mammal Protection Act are also considered as endangered/threatened if they are listed because “based on the best available scientific information, [the stock] is declining and is likely to be listed as a threatened species under the ESA within the foreseeable future.” However, marine mammal stocks listed as “strategic” because “the level of direct human-caused mortality exceeds the potential biological removal level,” or because they are listed as “depleted” under the Marine Mammal Protection Act, are instead classified as species of concern.

Exceptional importance to the ecosystem:
A species that plays a key role in the ecosystem that may be disrupted by typical levels of harvesting, including: keystone species (those that have been shown or are expected to have community-level effects disproportionate to their biomass), foundation species (habitat-forming species, e.g., oyster beds), basal prey species (including krill and small pelagic forage species such as anchovies and sardines), and top predators, where the removal of a small number of the species could have serious ecosystem effects. Species that do not fall into any of these categories but that have been demonstrated to have an important ecological role impeded by harvest (e.g., studies demonstrating trophic cascades or ecosystem phase shifts due to harvesting) shall also be considered species of exceptional importance to the ecosystem (Paine 1995; Foley et al. 2010).

FishBase vulnerability:
Cheung et al. (2005) used fuzzy logic theory to develop an index of the intrinsic vulnerability of marine fishes. Using certain life history parameters as input variables—maximum length, age at first maturity, longevity, von Bertalanffy growth parameter K, natural mortality rate, fecundity, strength of spatial behavior and geographic range—together with heuristic rules defined for the fuzzy logic functions, fish species were assigned to either a very high, high, moderate or low level of intrinsic vulnerability. In this framework, intrinsic vulnerability is also expressed with a numerical value from 1 to 100 with 100 being most vulnerable. This index of intrinsic vulnerability was then applied to over 1300 marine fish species to assess intrinsic vulnerability in the global fish catch (Cheung et al. 2007). FishBase, the online global database of fish, includes this numerical “vulnerability score” on the profiles of fish species for which this analysis has been conducted (Froese and Pauly 2010).

Fluctuating biomass:
If a stock is trending upwards (based on the most recent assessment) and has just recently exceeded the target reference point (TRP), it can be rated as **Very Low Concern**. If a stock is not trending but is truly fluctuating around the TRP (exceeding in some years and falling short in others, but with no clear trend), it can be rated as **Very Low Concern**. However, if a stock is fluctuating around the limit reference point (LRP), it cannot be considered **Very Low Concern**.

If a stock is trending downward and is currently below the TRP, the rating can be no better than **Low Concern**.

If a stock is below the LRP, it is considered **a High Concern**.

**Fluctuating fishing mortality:**

- If F is trending downwards, or was previously above $F_{MSY}$ (or a suitable proxy) but has recently gone below $F_{MSY}$ (in the most recent assessment), fishing mortality should be rated as **Low Concern**.
- If F is fluctuating around $F_{MSY}$, or if F has been consistently below $F_{MSY}$ and has just recently (in the latest assessment) risen above $F_{MSY}$ for just this one year (potentially due to management error or a new stock assessment and the consequent adjustment in reference points or estimates), fishing mortality should be rated as **Moderate Concern**.
- If F is trending upwards and has just risen above $F_{MSY}$, fishing mortality should be rated as **High Concern** unless there is a substantial plan to bring F back down. Such a plan would need to differ substantially from the existing harvest control rules (HCR), as those evidently did not keep F at a sufficiently low level.

**Highly appropriate management strategy:**

Management that is appropriate for the stock and harvest control rules takes into account major features of the species’ biology and the nature of the fishery. Such a management strategy incorporates the precautionary approach while also taking uncertainty into account and evaluating stock status relative to reference points, as these measures have been shown to be robust (modified from MSC 2010). As an example, if management is based on Total Allowable Catch, these limits are set below MSY and/or scientifically advised levels, accounting for uncertainty, and lowered if $B < B_{MSY}$. However, alternatives to TAC-based management, such as area-based (closures), 3S (size, sex and/or season limitations) or other appropriate methods may also apply (Appendix 4).

**Likelihood:**

**Highly likely:** 70% chance or greater, when quantitative data are available; may also be determined by analogy from similar systems when supported by limited data from the fishery and no scientific controversy exists (modified from MSC 2010 and based on guidance from MSC FAM Principle 2).

Examples of high likelihood for fishing mortality:

- All estimates of fishing mortality are within 70% or greater (e.g., 80% or 95%) confidence intervals, or all estimates of F from all scientifically feasible models and assumptions, are below $F_{MSY}$ or equivalent.

- Estimate of F is at 75% of sustainable levels of F (such as $F_{MSY}$) or less, or estimates of catch are < 75% MSY if the fishery is at or above $B_{MSY}$ (if F is fluctuating, see “fluctuating F” for more guidance).

- Exploitation is very low compared to natural mortality, mortality from other sources or population size.
Likely: 60% chance or greater, when quantitative data are available; may also be determined according to expert judgment and/or plausible argument (modified from MSC 2010 and based on guidance from MSC FAM Principle 2).

Probable: Greater than 50% chance; can be based on quantitative assessment, plausible evidence or expert judgment. Examples of “probable” occurrence for fishing mortality:

There may be some uncertainty or disagreement among various models; fishing mortality may be above 75% of a sustainable level and/or catch may be above 75% of a sustainable catch level (e.g., MSY) for stocks at B_{MSY}.

Historic high:
Refers to near-virgin biomass, or highest recorded biomass, if biomass estimates predate the start of intensive fishing. If a fishery has been historically depleted and then rebuilt, the rebuilt biomass is not considered a “historic high” even though it may be higher than historical levels.

Inherent vulnerability:
A stock’s vulnerability to overfishing based on inherent life history attributes that affect the stock’s productivity and may impede its ability to recover from fishing impacts. Marine finfish are considered highly vulnerable when their FishBase vulnerability score falls into the categories high “vulnerability”, “high to very high vulnerability”, or “very high vulnerability” (scores of 55 or above) based on the FishBase vulnerability score (derived from the formula in Cheung et al. 2005). All sea turtles, marine mammals, and seabirds are considered “highly vulnerable”. Marine invertebrates’ vulnerability is based on the average of several attributes of inherent productivity.

One of the first key papers on this subject (Musick 1999) summarizes the results of an American Fisheries Society (AFS) workshop on the topic and offers proposed low, medium and high “productivity index parameters” (for marine fish species) based on available life history information: the intrinsic rate of increase r, the von Bertalanffy growth function k, fecundity, age at maturity and maximum age. Notably, although a species’ intrinsic rate of increase is identified as the most useful indicator, it is also difficult to estimate reliably and is often unavailable (Cheung et al. 2005). To enable more timely and less data-intensive and costly identification of vulnerable fish species, Cheung et al. (2005) used fuzzy logic theory to develop an index of the intrinsic vulnerability of marine fishes based on life history parameters: maximum length, age at first maturity, longevity, von Bertalanffy growth parameter K, natural mortality rate, fecundity, strength of spatial behavior and geographic range (input variables). The index also uses heuristic rules defined for the fuzzy logic functions to assign fish species to one of the following groups: very high, high, moderate or low level of intrinsic vulnerability.

In this framework, intrinsic vulnerability is also expressed by a numerical value between 1 and 100 with 100 being most vulnerable. This index of intrinsic vulnerability was then applied to over 1300 marine fish species to assess intrinsic vulnerability in the global fish catch (Cheung et al. 2007). FishBase, the online global database of fish, uses the numerical value from this index as a “vulnerability score” on the profiles of fish species for which it has been evaluated (Froese and Pauly 2010).
Large portion of the stock is protected:
At least 50% of the spawning stock is protected, for example through size/sex/season regulations or the inclusion of greater than 50% of the species’ habitat in marine reserves. Future guidance will improve the integration of marine reserve science into the criteria, based on ongoing research.

Main species:
A species is included in the assessment as a main species if:
• The catch of the species in the fishery under assessment composes >5% of that fishery’s catch, or
• The species is >1% of that fishery’s catch and the fishery causes >5% of the species’ total mortality across all fisheries, or
• The species is <1% of that fishery’s catch and the fishery causes >20% of species’ total mortality across all fisheries, or
• The species is overfished, depleted, a stock of concern, endangered, threatened, IUCN Near Threatened, US MMPA strategic species, and/or subject to overfishing and the fishery causes >1% of species’ total mortality across all fisheries.
• If there are no other “main species” (based on the above guidance) besides the one assessed under criterion 1, but the total catch of other discarded and retained species is >5% (i.e. catch of criterion 1 species is <95% of total), assess the top 3 species by volume of catch (if there are only 1-2 other species caught, assess those species).

Managed appropriately:
Management uses best available science to implement policies that minimize the risk of overfishing or damaging the ecosystem, taking into account species vulnerability along with scientific and management uncertainty.

Negative genetic or ecological effects:
Hatchery supplementation of fisheries may have negative ecological effects, including competition between hatchery-raised and wild fish, as well as genetic effects, including reduced fitness of populations through genetic introgression and reduced genetic diversity (Kostow 2009; Araki and Schmid 2010). Other fishing practices may have additional detrimental genetic or ecological effects; for example, drifting Fish Aggregating Devices (FADs) may act as “ecological traps” that mislead fish into making maladaptive habitat choices that reduce their fitness (Hallier and Gaertner 2008). Unfortunately, these impacts are generally poorly understood for most fisheries, but where impacts are likely (i.e., where FADs are in use or where large-scale hatchery supplementation exists, as in most salmon fisheries), ecosystem-based management should include measures specifically designed, and in the best cases, proven to reduce these impacts.

Negligible:
Mortality is insignificant or inconsequential relative to a sustainable level of total fishing mortality (e.g., MSY or PBR); less than or equal to 5% of a sustainable level of fishing mortality.

No management:
A fishery with no rules or standards for regulating fishing catch, effort or methods. Management does not need to be enforced through government regulation or official management agencies but may also include voluntary action taken by the fishery, as long as there is general compliance.

Non-native species:
A non-native organism is an organism occurring outside its natural past or present range and dispersal potential, including any parts of the organism that might survive and subsequently reproduce, whose dispersal to the non-native area is caused by direct human action (e.g., introduced through ballast water or intentional translocation of organisms to a new area, but not including indirect anthropogenic effects, such as range shifts due to climate change). Modified from Falk-Petersen et al 2006.

Overfished:
A stock is considered “overfished” when exploited past an explicit limit where abundance is considered too low to ensure safe reproduction. In many fisheries, the term “overfished” is used when biomass has been estimated below a biological reference point used to signify an “overfished condition”. The stock may remain overfished (i.e., with a biomass well below the agreed limit) for some time even though fishing mortality may have been reduced or suppressed (FAO Glossary). Classification as “overfished” or “depleted” (including IUCN listing as “near threatened”, “special concern” and “vulnerable”) is based on evaluation by the management agency and/or FAO, but an analyst can use judgment to override this classification, especially where the classification may be out of date as long as there is scientific justification for doing so. Inclusion in the “overfished” category based on designations such as “stock of concern” are determined on a case-by-case basis, as such terms are not used consistently among management agencies. Stocks should be classified as “overfished” if the stock is believed to be at such a low level of abundance that reproduction is impaired or is likely to be below an appropriate limit reference point. Marine mammals classified as “depleted” under the Marine Mammal Protection Act also fall into this category if not listed as endangered or threatened. Stocks that are most likely (>50% chance) below the level where recruitment or productivity is impaired are also considered “overfished”. Note: Official IUCN listings should be overridden by more recent and/or more specific classifications where available (e.g., NMFS stock assessment showing that a stock is above target levels).

Overfishing:
A generic term used to refer to a level of fishing effort or fishing mortality such that a reduction of effort would, in the medium term, lead to an increase in the total catch; or, a rate or level of fishing mortality that jeopardizes the capacity of a fishery to produce the maximum sustainable yield on a continuing basis. For long-lived species, overfishing (i.e., using excessive effort) starts well before the stock becomes overfished. Overfishing, as used in the Seafood Watch® criteria, can encompass biological or recruitment overfishing (but not necessarily economic or growth overfishing).

- **Biological overfishing**: Catching such a high proportion of one or all age classes in a fishery as to reduce yields and drive stock biomass and spawning potential below safe levels. In a surplus production model, biological overfishing occurs when fishing levels are higher than those required for extracting the Maximum Sustainable Yield (MSY) of a resource and recruitment starts to decrease.
- **Recruitment overfishing**: When the rate of fishing is (or has been) high enough to significant reduce the annual recruitment to the exploitable stock. This situation is characterized by a greatly reduced spawning stock, a decreasing proportion of older fish in the catch and generally very low recruitment year after year. If prolonged, recruitment overfishing can lead to stock collapse, particularly under unfavorable environmental conditions.
- **Growth overfishing**: Occurs when too many small fish are being harvested too early through excessive fishing effort and poor selectivity (e.g., excessively small mesh sizes), and the fish are not given enough time to grow to the size at which maximum yield-per-recruit would be obtained from the stock. Reduction of fishing mortality among juveniles, or their outright protection, would lead to an increase in yield from the fishery. Growth overfishing occurs when the fishing mortality rate is above F_max (in a
yield-per-recruit model). This means that individual fish are caught before they have a chance to reach their maximum growth potential. Growth overfishing, by itself, does not affect the ability of a fish population to replace itself.

- **Economic overfishing**: Occurs when a fishery is generating no economic rent, primarily because an excessive level of fishing effort is applied in the fishery. This condition does not always imply biological overfishing.

(FAO Glossary; NOAA 1997)

**Precautionary approach:**
The precautionary approach involves the application of prudent foresight. Taking account of the uncertainties in fisheries systems and considering the need to take action with incomplete knowledge, the precautionary approach requires, inter alia: (i) consideration of the needs of future generations and avoidance of changes that are not potentially reversible; (ii) prior identification of undesirable outcomes and measures to avoid or correct them promptly; (iii) initiation of any necessary corrective measures without delay and on a timescale appropriate for the species’ biology; (iv) conservation of the productive capacity of the resource where the likely impact of resource use is uncertain; (v) maintenance of harvesting and processing capacities commensurate with estimated sustainable levels of the resource and containment of these capacities when resource productivity is highly uncertain; (vi) adherence to authorized management and periodic review practices for all fishing activities; (viii) establishment of legal and institutional frameworks for fishery management within which plans are implemented to address the above points for each fishery, and (ix) appropriate placement of the burden of proof by adhering to the requirements above (modified from FAO 1996).

**Productivity is maintained/not impaired:**
Fishing activity does not impact the stock, either through reduced abundance, changes in size, sex or age distribution, or reduction of reproductive capacity at age, to a degree that would diminish the growth and/or reproduction of the population over the long-term (multiple generations).

**Productivity–susceptibility analysis (PSA):**
Productivity-susceptibility analysis was originally developed to assess the sustainability of bycatch levels in Australia’s Northern Prawn fishery (Patrick et al. 2009), and has since been widely applied to assess vulnerability to fishing mortality for as number of fisheries worldwide. Productivity-susceptibility analysis is used by NOAA and the Australian Commonwealth Scientific Industrial Research Organization (CSIRO) to inform fisheries management. It also constitutes the basis of the risk-based framework used to evaluate data-poor fisheries under the Marine Stewardship Council Fishery Assessment Methodology (MSC FAM). The PSA approach allows the risk of overfishing to be assessed for any species based on predetermined attributes, even in the most data-poor situations.

The exact sets of productivity and susceptibility attributes vary between PSA methodologies, and different weighting of attributes can be employed based on relative contextual importance. Additionally, scoring thresholds can vary depending on the context in which PSA is employed. In the US methodology, productivity is defined as the capacity for a stock to recover once depleted, which is largely a function of the life history characteristics of the species. Generally, productivity attributes are similar to the life history parameters used for the above index of intrinsic vulnerability.

While PSA analysis is a widely accepted approach for evaluating risk of overexploitation of a fished species, for the purposes of Seafood Watch assessments it is useful to separate the productivity
attributes—which are intrinsic to a species and neither dependent on nor influenced by fishery practices—from the susceptibility attributes. Fisheries may influence the susceptibility of impacted stocks through the choice of gear, bait species, hook design, mesh size, area or seasonal closures, and other management measures. In addition, where detailed information on fishing mortality (e.g., estimates of F or harvest rates) is available, these data provide a more complete picture of the fishery impact that the susceptibility attributes are designed to predict. Therefore, under the revised Seafood Watch® criteria, the “inherent vulnerability” score will be derived from the FishBase vulnerability score, which address only those characteristics intrinsic to the species and equivalent to the productivity attributes considered under PSA. Susceptibility attributes will be separately considered as part of the evaluation of fishing mortality when more specific data are not available.

Because the FishBase vulnerability index has not been evaluated for application to marine invertebrates (Cheung, pers comm., 2011), we propose the use of “productivity” attributes from the PSA methodology used by the MSC, with adjustments to account for particular aspects of marine invertebrate life history (see Criterion Factors 1.1 and 2.1 for guidance).

Changes to PSA resilience attributes made to increase applicability to invertebrates include:

- Removal of “average maximum size” and “average size at maturity” attributes, as body size has been demonstrated not to correlate with extinction risk for marine invertebrates (McKinney 1997, Finnegan et al. 2009).
- Incorporation of fecundity in the average only if fecundity is low, as strong evidence suggests that high fecundity does not necessarily correlate with low vulnerability; however, low fecundity does seem to correspond with high vulnerability (Dulvy et al. 2003, Cheung et al. 2005).
- Removal of the “trophic level” attribute. Anecdotally, trophic level does not appear to be a strong predictor of extinction risk for marine invertebrates. Some of the most vulnerable marine invertebrates are at the lowest trophic level (e.g., abalone). Additionally, in a review of Canadian fishes, trophic level was not found to be a strong predictor of extinction risk in marine fishes (O’Malley 2010; Pinsky et al. 2011).
- Incorporation of density dependence, particularly the existence of depensatory dynamics, or Allee effects, for small populations. Allee effects may have a profound effect on the resilience of marine invertebrates to fishing mortality (Hobday et al. 2001, Caddy 2004).

**Reasonable timeframe (for rebuilding):**
Dependent on the species’ biology and degree of depletion, but generally within 10 years, except in cases where the stock could not rebuild within 10 years even in the absence of fishing. In such cases, a reasonable timeframe is within the number of years it would take the stock to rebuild without fishing, plus one generation, as described in Restrepo et al. (1998).

**Recruitment is impaired:**
Fishing activity impacts the stock—either through reduced abundance, changes in size, sex or age distribution, or reduction of reproductive capacity at age—to a degree that will diminish the growth and/or reproduction of the population over the long-term (multiple generations); or, the stock is below an appropriate limit reference point, if one is defined.
Regularly monitored:
Fishery-independent surveys of stocks, or other reliable assessments of abundance, are conducted at least every three years.

Reliable data:
Data produced or verified by an independent third party. Reliable data may include government reports, peer-reviewed science, audit reports, etc. Data are not considered reliable if significant scientific controversy exists over the data, or if data are old or otherwise unlikely to represent current conditions (e.g., survey data is several years old and fishing mortality has increased since the last survey).

Species of concern:
Species about which management has some concerns regarding status and threats, but for which insufficient information is available to indicate a need to list the species as endangered. In the U.S., this may include species for which NMFS has determined, following a biological status review, that listing under the ESA is "not warranted," pursuant to ESA section 4(b)(3)(B)(i), but for which significant concerns or uncertainties remain regarding their status and/or threats. Species can qualify as both "species of concern" and "candidate species" (http://www.nmfs.noaa.gov/pr/glossary.htm#s). In addition, marine mammal stocks listed as “strategic” under the Marine Mammal Protection Act are classified as species of concern. The terms “species of concern” or “stock of concern” are used similarly by other federal and state management bodies.

Stakeholder input:
A stakeholder is an individual, group or organization that has an interest in, or could be affected by, the management of a fishery (modified from MSC 2010). Stakeholder input may include: involvement in all key aspects of fisheries management from stock assessment and setting research priorities to enforcement and decision-making. In addition, stakeholders may take ownership of decisions and greater responsibility for the wellbeing of individual fisheries (Smith et al 1999). Effective stakeholder engagement requires that the management system has a consultation processes open to interested and affected parties and that roles and responsibilities of the stakeholders are clear and understood by all relevant parties (modified from MSC 2010).

Stock:
A self-sustaining population that is not strongly linked to other populations through interbreeding, immigration or emigration. A single fishery may capture multiple stocks of one or multiple species. Stocks can be targeted or non-targeted, retained or discarded, or some combination thereof (e.g., juveniles are discarded and adults are retained).

Ideally, the management unit of “stock” should correspond to the biological unit. However, often the fisheries management unit of “stock” may not be the same as the biological unit. If multiple biological stocks are managed as one, and there is insufficient information to assess the stock status of each biological stock, the management unit is assessed. This situation detracts from the fishery’s “quality of information” score, as it makes it impossible to assess individual stocks’ health. If management occurs on a finer scale than biological stocks so that multiple management unit stocks compose one interbreeding population, the health and abundance of the biological stock should be assessed as a whole based on information aggregated across the management units. The effectiveness of management can be assessed at the finest scale for which meaningful and verifiable differences in management practice exist.

Substantial contributor:
A fishery is a substantial contributor to impacts affecting a population, ecosystem or habitat if the fishery is a main contributor, or one of multiple contributors of a similar magnitude, to cumulative fishing mortality. Examples of a fishery that is not a substantial contributor include: (a) catch of the species is a rare or minor component of the catch in this fishery and the fishery is a small contributor to cumulative mortality, relative to other fisheries. However, if there has been a jeopardy determination for that stock in the fishery being assessed it should be considered a substantial contributor regardless of this definition.

**Substantial proportion of habitat:**
Refers to a condition when at least 20% of each representative habitat (where representative habitats can be delineated by substrate, bathymetry, and/or community assemblages), within both the range of the targeted stock(s) and the regulatory boundaries of the fishery under consideration (i.e., within the national EEZ for the fishery under consideration), is completely protected from fishing with gear types that impact the habitat in that fishery.

**Susceptibility (low/moderate/high)**
A stock’s capacity to be impacted by the fishery under consideration, depending on factors such as the stock’s likelihood to be captured by the fishing gear. The susceptibility score is based on tables from MSC’s Productivity-Susceptibility Analysis framework (see Appendix 2). Examples of low susceptibility include: low overlap between the geographic or depth range of species and the location of the fishery; the species’ preferred habitat is not targeted by fishery; the species is smaller than the net mesh size as an adult, is not attracted to the bait used, or is otherwise not selected by fishing gear; or strong spatial protection or other measures in place specifically to avoid catch of the species.

**Sustainable level (of fishing mortality):**
A level of fishing mortality that will not reduce stock below the point where recruitment is impaired, i.e., above F reference points, where defined. The F limit reference points should be around either F_{MSY} or F_{35–40%} for moderately productive stocks; low productivity stocks like rockfish and sharks require F in the range of F_{50–60%} or lower. Higher F values require a strong scientific rationale. The F reference points are limit reference points, so buffers should be used to ensure that fishing mortality does not exceed these levels. Where F is unknown but MSY is estimated, fishing mortality at least 25% below MSY is considered a sustainable level (for fisheries that are at or above B_{MSY}).

**Up-to-date data/stock assessment:**
Complete stock assessments are not required every 1–3 years, but stocks should be regularly monitored at least every 1–3 years, and stock assessments should be based on abundance and fishing mortality data not more than three years old. Data may be collected by industry, but analysis should be independent.

**Very limited area:**
Fishing (with damaging gear, when assessing Criterion D) is limited to no more than 50% of each representative habitat (where representative habitats can be delineated by substrate, bathymetry, and/or community assemblages) within both the range of the targeted stock(s) and the regulatory boundaries of the fishery under consideration (e.g., the national EEZ for the fishery under consideration).

**Very low levels of exploitation (e.g., experimental fishery):**
Fishery is under-exploited or is being conducted experimentally to collect data or gauge viability, such that exploitation rates are far below sustainable yields (e.g., 20% or less of sustainable take). Alternatively, when no other information is available, exploitation levels may be considered very low if a
fishery falls into the “low” category for all “susceptibility” questions under Productivity-Susceptibility Analysis (see Appendix 2 for more details on scoring susceptibility).

Appendices

Appendix 1 – Further guidance on interpreting the health of stocks and fishing mortality

The tremendous variability among fisheries, data availability and stock assessment methods makes it impossible to define specific appropriate reference points that would be applicable to all assessed fisheries. Instead, criteria are based on the commonly accepted management goal that target biomass should be at or above the point where yield is maximized, and management should ensure a high probability that biomass is at or above a limit reference point (where below which recruitment or productivity of the stock would might be impaired). Three common types of reference points are MSY-based, SPR-based, and ICES reference points. However, other reference points may be used in some fisheries, and should be evaluated in accordance with the management goal articulated above.

**MSY-based reference points**

While the concept of MSY is far from perfect, MSY-based biomass and fishing mortality reference points are commonly used in some of the most well managed fisheries around the world. When applied appropriately, these reference points are an important tool for maintaining stock productivity in the long term. However, without properly accounting for scientific and management uncertainty, maintaining a stock at B_{MSY} (the biomass corresponding to MSY) and harvesting at MSY runs a high risk of unknowingly either overshooting MSY or allowing biomass to drop below B_{MSY} without reducing harvest rates and thus inadvertently overharvesting (Roughgarden and Smith 1996; Froese et al. 2010). The risk of impacts from inadvertent overharvesting increases with increased uncertainty and with increased inherent vulnerability of the targeted stock. To account for these interactions, the guidance provided for assessing stock health and fishing mortality is based on MSY reference points but requires high scientific confidence that biomass is above target levels and that fishing mortality is below MSY.

Proxies for B_{MSY} are acceptable if shown to be conservative relative to B_{MSY} for that stock, or if they fit within the guidelines for appropriate target level*. Where B_{MSY} or proxy reference points are not known or are not applicable, the stock/population health criteria can be interpreted using relevant indicators that are appropriate as targets and safe limits for abundance of the species (e.g., escapement relative to escapement goals can be evaluated in lieu of biomass relative to limit reference points).

**SPR-based reference points**

In the absence of stock assessments and MSY-based reference points, the stock health can be evaluated based on CPUE, trends in abundance and size structure, and/or simple, easy to calculate reference points such as Fraction of Lifetime Egg Production (FLEP) (equivalent to Spawning Potential Ratio, SPR). Other data-poor or alternative assessment techniques that provide evidence that stocks are healthy (i.e., productivity and reproduction are not impaired) may be used in place of reference points. Guidelines may be added on a continuing basis, but they must be demonstrated to be accurate indicators of stock health. Guidance for assessing stock health and fishing mortality for data-poor stocks is based on O’Farrell and Botsford (2005) and Honey et al. (2010) but can be addressed on a case-by-case basis with a goal of ensuring that data-poor fisheries are held to the same standard of likelihood as data-rich fisheries when stocks are above a level where recruitment would be impaired and fishing mortality is at or below a sustainable level of harvest.

*Underlined terms have been defined in the glossary. Ctrl + Click to view.
Examples of evidence that a stock is above the point where recruitment or productivity is impaired. i.e. an appropriate limit reference point, include:

- The current lifetime egg production (LEP) or spawning per recruit (SPR) is above an appropriate SPR or Fraction of Lifetime Egg Production (FLEP)-related reference point;
- Spawning potential is well protected (e.g., females are not subject to mortality, and it can be shown or inferred that fertilization is not reduced);
- Quantitative analyses conducted by fishery scientists under transparent guidelines indicate sufficient stock.

Strong, quantitative scientific evidence from the fishery under consideration is required to consider a stock a “very low concern”. When limited data are available from the fishery, analogy with similar systems, qualitative expert judgments and/or plausible arguments may be used to consider the stock “low concern”.

Use of CPUE requires the absence of hyperstability, that CPUE is proportional to abundance (or adjusted), and that there have been no major changes in technology.

If relying on CPUE rather than a LEP-based reference point, trends in size structure are also needed to ensure the fishery is not reducing stock productivity by depleting the relative proportion of large individuals.

The LEP can be estimated from length frequency data from both unfished (or marine reserve) and current populations, and does not require catch-at-age data. Reference points based on FLEP should be considered limit reference points.

For “very low concern” ratings, there must be evidence that productivity has been reduced through fisheries-induced changes in size or age structure, size or age at maturity, sex distribution, etc.

ICES reference points
The ICES reference points Fpa, Flim, Bpa, and Blim are not equivalent to MSY-based reference points. In fact, comparisons have demonstrated that Fpa is typically above FMYS and Bpa is typically below BMYS, such that MSY-based reference points are generally more conservative (ICES 2010). In many cases, Bpa is well below BMYS and even below 1/2BMYS (Kell et al. 2005). Therefore, guidance for evaluating stock health using Bpa and fishing mortality using Fpa is conservative, accounting for the difference between these reference points and MSY-based reference points. ICES plans to transition to an MSY-based approach by 2015 (ICES 2010). If B>Bpa or F>Fpa, the stock should score as a moderate concern, unless a good reason exists to justify a “low concern” score (i.e., either the reference points have been shown to be conservative or the biomass is well above reference points).

Proxies
For many fisheries, FMYS and BMYS are unknown, and proxies are often used. Most commonly, biomass proxies are based on the percent of unfished or virgin biomass (B0). Fishing mortality proxies are often based on spawning potential ratio (SPR).

Commonly used and acceptable biomass reference points are typically 35–40% of B0 for most stocks (Clark 1991; NZ Ministry of Fisheries 2008). This target may vary according to stock productivity.
however, justifications for lower target levels are often based on assumptions about “steepness”\(^6\) that may be highly uncertain or poorly understood. It is now recognized that stock targets lower than approximately 30-40\% of B\(_0\) are increasingly difficult to justify (NZ Ministry of Fisheries 2008). For these targets to be considered appropriate reference points, solid scientific justification is required. In addition, stocks reduced to this target level or below (equivalent to removing more than 60–70\% of the stock’s biomass) would be unlikely to achieve the ecosystem-based management goal of allowing a stock to fulfill its ecological role and should be scored accordingly under ecosystem-based management.

Alternatively, when unfished biomass cannot be estimated, proxy biomass reference points may be based on the equilibrium biomass achieved using appropriate fishing mortality reference points, as described below.

A large body of scientific literature addresses appropriate fishing mortality reference points based on spawner biomass per recruit (SPR). Ideally, these should be shown through scientific analysis to be at or above replacement % SPR (the threshold level of SPR necessary for replacement) for the species, based on its productivity and S-R relationship (viz. Mace and Sissenwine 1993). However, for many species this analysis will not be available. In these cases, guidance is based on the conclusions of numerous analyses demonstrating that, in general, F\(_{35-40}\%) (the fishing mortality rate that reduces the SPR to 35–40\% of unfished levels) is appropriate for species with moderate vulnerability, while a more conservative fishing mortality rate of about F\(_{50-60}\%) is needed for highly vulnerable species such as rockfish and sharks [Botsford and Parma 2005; Mace and Sissenwine 1993; Clark 2002; Myers et al. 1999; Goodman et al. 2002].

Evaluating Fishing Mortality

Evaluation of fishing mortality should reflect the mortality caused by the fishery, but in the context of whether cumulative impacts on the species (including mortality from other fisheries) are sustainable. When determining whether a fishery is a substantial contributor, err on the side of caution. Unknown or missing data are grounds for classification as a substantial contributor.

Reference points

Generally, species should be managed with reference points that fit the definition of a sustainable level of fishing mortality and/or an appropriate SPR or Fraction of Lifetime Egg Production (FLEP)-related reference point. Species that are not commercially fished or managed but make up non-target catch in the fishery will generally not have reference points defined. In lieu of reference points, these stocks should be evaluated relative to a level of mortality scientifically shown not to lead to depletion of the stock. For species with high vulnerability, the reference point must be demonstrated to be appropriate for that species’ biology. As a rule of thumb, F\(_{40}\%) is not precautionary enough for high vulnerability species; F\(_{50}\% or lower is more appropriate when using SPR-based proxies.

ICES reference points

Because analysis has shown that the ICES reference point F\(_{pa}\) is typically above F\(_{MSY}\), ICES stocks using F\(_{pa}\) as a reference point must be rated more conservatively than stocks using F\(_{MSY}\). If F > F\(_{pa}\), rate the stock as “high concern.” If F < F\(_{pa}\), rate the stock as “moderate concern,” unless there is additional evidence that F is below a sustainable level such as F\(_{MSY}\).

---

\(^6\) Steepness is a key parameter of the Beverton-Holt spawner-recruit model that is defined as the proportion of unfished recruitment produced by 20\% of the unfished spawning biomass. Steepness is difficult to estimate, and the calculation of reference points is often very sensitive to estimates of steepness.
**Data-poor stocks**

When no reference points are available (i.e., in data-poor fisheries), fishing mortality can be evaluated based on the likelihood that management actions and characteristics of the fishery constrain fishing mortality to acceptable levels. For example, fishing mortality could be considered a low concern if the fishery has a low likelihood of interacting with a non-target species due to low overlap between the species range and the fishery, or due to low gear selectivity for the species (resulting in low susceptibility; see below). Fishing mortality on target or non-target species may be considered a low concern if there is a very low level of exploitation, as in an experimental emerging fishery, or if a large portion of the stock’s key habitat is protected in no-take reserves that have been shown to effectively protect the species. We hope to incorporate the results of ongoing research to provide more specific guidance on the amount of habitat that should be protected in marine reserves. In the interim, however, in order to score fishing mortality as a very low concern in the absence of reference points or other information about fishing mortality rates, at least 50% of all representative habitats should be protected in Marine Protected Areas where the assessed stock experiences no fishery mortality.

**Appendix 2 – Susceptibility attributes from the MSC FAM**

Where no information on fishing mortality is available in a data-poor fishery, susceptibility may be used as a proxy (see Factor 1.3). The concept of susceptibility is based on the “Susceptibility” attributes from the Productivity-Susceptibility Analysis (PSA) used in the MSC Certification Requirements document (2012). The susceptibility attributes and scoring guide from the MSC are given below. “Selectivity” should be scored only once for the appropriate gear type; where no cut-offs for a particular gear type are provided, the analyst shall develop similar selectivity tables that are appropriate for the gear and shall include a justification for the factors used and cut-offs selected in these cases.

Instructions for use: for each species in each fishery, score each attribute of susceptibility below. The final susceptibility score is the arithmetic mean of each attribute, and is considered “low” susceptibility overall if the final score is <=1.5, moderate if between 1.5 and 2.5, and high if >=2.5

<table>

Appendix 3 – Matrix of bycatch impacts by gear type

The matrix shown in this appendix is used to determine the relative impact of a fishery on bycatch species of various taxa for fisheries where species and amounts of bycatch are not available or are incomplete. The matrix represents typical relative impacts of different fishing gear on various taxa based on the best available science. The values in the matrix were developed initially by averaging the findings of two studies that ranked the relative ecological impacts of fishing gear (Fuller et al. 2008; Chuenpagdee et al. 2003). Some values in the matrix have been updated based on a survey of scientific experts on bycatch from around the world to increase the global relevance of the matrix.

The findings of the studies used to construct this matrix were pulled from literature searches, fisheries data and expert opinion. In general, these studies ranked the severity of fishing gear impacts as shown in this table (in order of severity):

Because these studies were based on fisheries operating in Canadian and United States waters, we also conducted a review of literature and expert opinion on bycatch severity by gear type from different regions of the world. Some of the initial values from Fuller et al. (2008) and Chuenpagdee et al. (2003) were adjusted accordingly. These changes are intended to better reflect the array of bycatch issues that occur using the same gear types in different regions of the world. For example, we increased the potential severity of bycatch of seabirds for trawlers operating in regions where there is a high occurrence of albatross and petrel interaction based on studies that found (1) seabirds may collide with net monitoring (net sonde) cables and trawl warps, and (2) seabirds can become entangled in the net (while attempting to feed) when the trawl is at the surface during setting and hauling (Weimerskirch et al. 2000; Wienecke and Robertson 2002; Sullivan 2006; Bull 2007; Abraham et al. 2008).

In addition, we increased the potential severity of midwater trawl impacts on marine mammals based on the study of DuFresne et al. (2007), which found fishing depth (midwater) to be the most important predictor of common dolphin bycatch. Another study by Fertl and Leatherwood (1997) found more cetaceans caught in midwater than bottom trawls. Also, pinniped species have been shown to use trawl fisheries for food and may become trapped in nets and drown (Fertl & Leatherwood 1997; Morizur et al. 1999; Rowe 2007). For example, New Zealand fur seals are attracted to the physical presence of fishing vessels and are thought to become caught when the net is being shot or during hauling (Baird & Bradford 2000).
Bycatch severity for biogenic habitats (coral and sponges) by gear type was determined by averaging the values given in Fuller et al. (2008) and Chuenpagdee et al. (2003). In Chuenpagdee et al. (2003), this category was named “biological habitat” and in Fuller et al. (2008) it was called “coral and sponges.” We did not change these values because it is likely that gear types that contact the bottom have the same potential for severe impacts throughout the world’s oceans. Impacts from fishing on the benthos occur on virtually all continental shelves worldwide (Watling 2005).

We increased the number of trawl types from only bottom and midwater (used in both Fuller et al. (2008) and Chuenpagdee et al. (2003)) to also include bottom trawl categories for tropical/subtropical fish, tropical/subtropical shrimp, coldwater fish, and coldwater shrimp. Shrimp trawls are not designed to drag along the bottom and herd fish, so they receive a lower impact score in the matrix for finfish bycatch. The turtle bycatch score was increased for tropical trawls to account for the severe threats to turtles posed by bottom trawling in tropical waters worldwide.

Other changes to the findings of Fuller et al. (2008) and Chuenpagdee et al. (2003) include separating the different purse seine techniques into FAD/log sets, dolphin/whale sets and unassociated school sets based on the variable bycatch rates found in a study by Hall (1998). Hall (1998) found that log (FAD) sets have the overall greatest bycatch for some species, followed by school sets and dolphin sets. Turtle bycatch potential was derived from research by Wallace and Lewison (2010).

Bottom seines or demersal seines (including Danish seines, Scottish fly-dragging seines and pair seines) were not included in the Fuller et al. (2008) and Chuenpagdee et al. (2003) studies because these gear types are not commonly used in the U.S. or Canada. Like purse seines, these gear types are used to encircle a school of fish, but they are operated in contact with the seafloor. A study by Palsson (2003) compared haddock discards among three demersal gear types in Icelandic waters and found fish bycatch to be lowest in Danish seines when compared with demersal trawls and longline gear. Danish seines targeting benthic fish species can incidentally catch non-target species such as flounder, cod, and haddock (Icelandic Ministry of Fisheries 2010). Alverson et al. (1996) found that Danish seines generally fell into a low-moderate bycatch group of gear, with lower bycatch ratios than the majority of gear types, including bottom trawls, longlines and pots, but with higher bycatch than pelagic trawls and purse seines. Based on these findings, the bycatch score of Danish seines was estimated from the score for purse seines with an increase in the effects on shellfish to account for Danish seines being operated on the seafloor, an increase in the effect on finfish to account for greater bycatch of benthic fish such as flatfish, cod and haddock, and a decrease in the effect on forage fish, which are typically pelagic.
Unknown bycatch matrix

Highest impacts receive a score of 1 and lowest impacts receive a score of 5. Key: B = Bottom, P = Pelagic, M = Mid-water, BTF = Bottom tropical fish, BTS = Bottom tropical shrimp, BCF = Bottom coldwater fish, BCS = Bottom coldwater shrimp, PF = Purse FAD/log (tuna), PD = Purse dolphin/whale (tuna), PU = Purse unassociated (tuna), Pot = Pot and trap, HD = Harpoon/diver, TP = Troll/pole and line

Additional guidance for unknown bycatch species

**Sea turtles – all endangered/threatened:** See Wallace et al. (2010) for global patterns of marine turtle bycatch. In addition, a global program, Mapping the World’s Sea Turtles, created by the SWOT (State of the World’s Sea Turtles) database is a comprehensive global database of sea turtle nesting sites around the world. The SWOT map is highly detailed and can be customized, allowing location filters and highlights of both species and colony size with variously colored and shaped icons. This map together with the paper by Wallace et al. (2010) can help to determine if the fishery being assessed has potential interactions with sea turtles.

**Sharks, marine mammals and seabirds:** Identify whether the fishery overlaps with any endangered/threatened or overfished species and err on the side of caution if species-specific and geographic information is inconclusive. For example, if shark populations are data deficient, err on the side of caution and rate as “overfished” or “depleted”.

**Sharks:** Select “overfished” or “depleted”, when data deficient or select “endangered/threatened” when data exist to support this (see Camhi et al. 2009). Globally, three-quarters (16 of 21) of oceanic pelagic sharks and rays have an elevated risk of extinction due to overfishing (Dulvy et al. 2008). See Camhi et al. (2009) for geographic areas, IUCN status and conservation concerns by shark species. Table 1 illustrates additional resolutions, recommendations and conservation and management measures by RFMO for sharks. Additional region and species-specific shark conservation information associated follows Table 1 in list format (Camhi 2009; Bradford 2010).

**Marine mammals:** The global distribution marine mammals and their important conservation areas are given by Pompa et al. (2011), who also used geographic ranges to identify 20 key global conservation sites for all marine mammal species (123) and created range maps for them (Figure 1; Table 2; Pompa et al. 2011 and supplt.).

**Seabirds:** Figures 2 and 3 illustrate the distribution of threatened seabirds throughout the world (Birdlife International 2011). Also see Birdlife International (2010) to locate Marine Important Bird Areas (MIBA). Albatross are the most highly threatened family, with all 22 species either globally threatened or near threatened. The penguins and shearwaters/gadfly petrels also contain a high proportion of threatened species (Birdlife International 2010).

**Teleost fish species: Unknown** (a Moderate Concern) unless data exist that would indicate an alternative rating.
Table 1. Active resolutions, recommendations, and conservation and management measures by RFMO for sharks. Table from Camhi et al. (2009).  * ICCAT = International Commission for the Conservation of Atlantic Tunas; NAFO = North Atlantic Fisheries Organization; GFCM = General Fisheries Commission for the Mediterranean; SEAF0 = South East Atlantic Fisheries Organization; IATTC = Inter-American Tropical Tuna Commission; WCPOC = Western and Central Pacific Fisheries Commission; IOTC = Indian Ocean Tuna Commission; CCAMLR = Commission for the Conservation of Antarctic Marine Living Resources.  b The weight of recommendations and resolutions varies by RFMO. For example, all ICCAT recommendations are binding, whereas resolutions are not.

Additional shark information and citations (Bradford 2010)

- In the Gulf of Mexico, Baum and Myers (2004) found that between the 1950s and the late-1990s, oceanic whitetip and silky sharks (formerly the most commonly caught shark species in the Gulf of Mexico) declined by over 99 and 90%, respectively.
- In the Northwest Atlantic, Baum et al. (2003) estimated that scalloped hammerhead, white, and thresher sharks had declined by over 75% between the mid 1980s and late 1990s. The study also found that all recorded shark species in the Northwest Atlantic, with the exception of mako sharks, declined by over 50% during the same time period.
- Myers et al. (2007) reported declines of 87% for sandbar sharks, 93% for blacktip sharks, 97% for tiger sharks, 98% for scalloped hammerheads, and 99% or more for bull, dusky, and smooth hammerhead sharks along the Eastern seaboard since surveys began along the coast of North Carolina in 1972.
- The International Union for the Conservation of Nature (IUCN) has declared that “32% of all pelagic sharks and rays are Threatened.” The IUCN has declared another 6% to be Endangered, and 26% to be Vulnerable.
- In the Mediterranean Sea, Ferretti et al. (2008) found that hammerhead, blue, mackerel, and thresher sharks have declined between 96 and 99.99% relative to their former abundance levels.
- Ward and Myers (2005) report a 21% decline in abundance of large sharks and tunas in the tropical Pacific since the onset of commercial fishing in the 1950s.
- Meyers and Worm (2005) indicate a global depletion of large predatory fish communities of at least 90% over the past 50–100 years. The authors suggest that declines are “even higher for sensitive species such as sharks.”
- Dulvy et al. (2008) state that “globally, three-quarters (16 of 21) of oceanic pelagic sharks and rays have an elevated risk of extinction due to overfishing.”
- Graham et al. (2001) found an average decrease of 20% in the catch rate of sharks and rays off New South Wales, Australia, between 1976 and 1997.

Appendix 4 – Appropriate management strategies
Appropriate management procedures may vary greatly between different fisheries, regulatory frameworks and species. To some extent, assessment of harvest control rules and other management strategies must therefore be addressed on a case-by-case basis. However, general guidelines for appropriate management are still relevant and useful. For fisheries managed using catch limits or TACs, these guidelines have been derived largely from the guidance provided for implementation of the Magnuson-Stevens Fishery Conservation and Management Act used for fishery management in the U.S. (Restrepo and Powers 1998; Restrepo et al. 1998). While other countries have different regulatory frameworks, similar strategies to those suggested in Restrepo et al. (1998) are used throughout the world where stock assessments are available and catch limits are employed (e.g., Australian Department of Agriculture, Fisheries and Forestry 2007; NZ Ministry of Fisheries 2008; DFO 2009). Commonly accepted strategies include setting fishing mortality rates safely below F_{MSY} (or equivalent) to account for uncertainty; reducing F when stocks fall below biomass target reference points (generally around B_{MSY} or 40% of unfished biomass); and reducing fishing mortality when stock falls below a critical level where recruitment is impaired. Management reference points are assumed to be valid unless scientific information exists to suggest otherwise, e.g., a scientific assessment or controversy that strongly suggests current reference points are not appropriate for the species under assessment.

In general, the minimal attributes of an appropriate management strategy include:

1. A process for monitoring and conducting “assessments” (not necessarily formal stock assessments). Monitoring should occur regularly, though the frequency of assessments needed may vary depending on the variability of the stock.
2. Rules that control the intensity of fishing activity or otherwise ensure the protection of stock productivity.
3. A process to modify rules according to assessment results, as needed.

Some effective management strategies

For data-rich or data-moderate stocks that have quota-based management, a “highly effective” management strategy is one that:

- Incorporates an up-to-date, scientific stock assessment that allows managers to determine if stocks are healthy and to set appropriate quotas;
- Uses appropriate limit and target reference points for stock and fishing mortality;
- Chooses risk-averse policies rather than risky, yield-maximizing policies;
- Includes buffers in the TAC to account for uncertainty in stock assessments
  - Set Allowable Biological Catch (ABC) and Annual Catch Limit (ACL) at less than the Over-Fishing Level (OFL = long term mean of MSY) to account for scientific uncertainty (survey data on stock size, etc. can reduce scientific uncertainty);
  - Set Total Allowable Catch (TAC) at less than ABC to account for management uncertainty (monitoring catch, etc. can reduce management uncertainty);
  - As a rule of thumb, TAC should have less than 30% p* (likelihood) of exceeding OFL; or TAC should be set such that F is 25% below the threshold fishing pressure, e.g. F_{MSY} (Restrepo et al. 1998)
  - Stocks with low biomass, high vulnerability, and high uncertainty warrant greater protection against overfishing (e.g., more conservative harvest control rules/ greater buffers in setting TAC and/or closer monitoring of stocks).
- Takes into account other sources of mortality (e.g., recreational fishery, bycatch of juveniles, etc.) and environmental factors that affect stock, such as oceanographic regime;
• Incorporates a strategy for maintaining or rebuilding stock productivity:
  o A no-fishing point when biomass is below the limit reference point;
  o A decrease in F when biomass is below the target reference point or is declining
    (whether declines are due to fishery or environmental factors).
• Employs an effective strategy to prevent overcapitalization;
• Has been demonstrated effective (e.g., stock productivity has been maintained over multiple
  generations), or if stock productivity has not been maintained or is declining, have adjusted
  management accordingly.

Effective management in data-poor fisheries
(more information on data-poor evaluation methods below)

Whether managed stocks are data-rich or data-poor, management must include a strategy to ensure
that stock productivity is maintained in order to be considered effective. This strategy should include a
process for monitoring and conducting “assessments” of some kind (not necessarily formal stock
assessments), rules that control the intensity of fishing activity or otherwise ensure the protection of a
portion of the spawning stock, and a system of adaptive management, such that rules are modified
according to assessment results, as needed (Smith et al. 2009; Phipps et al. 2010).

There are some relatively reliable methods for setting catch limits in data-poor fisheries, including: An
Index Method (AIM), which involves fitting a relationship between population abundance indices and
catch; Depletion-Corrected Average Catch (DCAC), which allows managers to estimate a sustainable
yield based on average catch over a set time period, adjusting for initial declines in abundance due to
harvesting; and extrapolation methods, or relying on inferences from related or “sister” stocks, with the
use of precautionary buffers in case the data-poor stocks are more vulnerable than the related data-rich
stocks (Honey et al. 2010). Other techniques recommended for data-poor stocks include the use of
productivity-susceptibility analysis (PSA) to highlight stocks that are particularly vulnerable to over-
exploitation (Patrick et al. 2009; Honey et al. 2010) and setting catch limits based on historical catch
from a period of no declines, with targets set at 75% of average catch if biomass is believed to be
healthy, 50% of average catch if biomass is expected to be below target levels but above the point
where recruitment would be impaired, and 25% of average catch if the stock is depleted (Restrepo and

Other than constraining fishing mortality (e.g., through TACs), fisheries may be credited for employing
alternative strategies that are widely believed to be help maintain stock productivity. Some examples of
effective alternative strategies are spatial management, including protecting a large proportion of
coastline in reserves and/or protecting known spawning aggregations with seasonal or spatial closures
(e.g., Johannes 1998), or protecting females, which preserves the spawning per recruit of the population
as long as fertilization does not decrease (e.g., Dungeness crab; Chaffee et al. 2010). Finally, stocks may
be subject to low mortality in a data-poor fishery as a result of low susceptibility, e.g., if the species is
small enough to fit between the mesh of the nets or is not attracted to the type of bait used (low
susceptibility is generally more applicable as protection for non-target stocks).

Management of data-poor stocks – alternatives to MSY-based management

For data-poor stocks, management should:
Include a process for monitoring and assessment, such as recording trends in CPUE and size structure, or estimating FLEP, or comparison of abundance index to historical high (see glossary), unfished, or marine reserve levels:

- Trends in CPUE are appropriate only if technology has not changed, there is no hyperstability, and abundance is shown to be proportional to CPUE;
- Trends in size structure must also be monitored to avoid depletion of large individuals.

Include a strategy for protecting spawning stock, such as:

- Estimate sustainable yield based on Depletion Corrected Average Catch (DCAC), An Index Method (AIM), or another accepted strategy;
- Protect a large portion of spawning stock in marine reserves (at least 50%, including important spawning areas if applicable) or close hotspots to fishing (for bycatch species);
- Enforce size, sex, and/or season limitations that are likely to be effective in protecting spawning stock productivity (e.g., Dungeness crab 3-S management);
- Extrapolate based on data-rich related or “sister” stocks, with precautionary buffers in place to account for potential differences in the stocks’ life histories;
- Maintain exploitation rates at very low levels (e.g., experimental fishery) until more data can be collected, or
- Base TAC on average historical catch during a period of time with no declines in abundance (TAC should be set at no more than 75% of average catch if stock is believed to be healthy, 50% if believed to be below target levels, and 25% if believed to be overfished. Note: as there is generally no data to assess whether a stock is healthy, TAC should not be more than 50% of historical catch unless there is a strong scientific reason to believe that stocks are above BMSY).

Allow for adaptive management so that fishing strategy is adjusted if assessment/monitoring indicates that stock is declining or below target levels;

Have been demonstrated effective (e.g., stock productivity has been maintained over multiple generations) or, if stock productivity has not been maintained or is declining, management has been adjusted accordingly.

Procedures for monitoring/assessing stocks and procedures for protecting spawning stock must be in place, and be demonstrated effective, to qualify management strategy as “highly effective”. If measures are expected to be effective, e.g., through analogy with similar systems, but have not been demonstrated effective in this fishery, management is “moderately effective”. If measures are not expected to be effective, management strategy is “ineffective”.

Appropriate management also depends on the conservation concern associated with the stock. In addition to the precautionary elements listed above, stocks that are endangered or threatened also require a recovery plan and/or best management practices designed and demonstrated to reduce mortality and allow the stock to recover. Overfished and depleted stocks require a rebuilding plan.

Data–poor fishery evaluation methods

*Sequential trend analysis (index indicators)*

Sequential analysis comprises a broad suite of techniques used to analyze time series data in order to detect trends in a variable (or in various indices) and infer changes in the stock or population. Sequential analyses can encompass a wide range of data types and requirements (Honey et al. 2010). Examples
include: DCAC, time series of catch statistics, survey/weight/length-based reference points, trophic indices, and spawning potential ratio (SPR) analogues (Honey et al. 2010).

Depletion-corrected average catch (DCAC) uses only catch time-series data supplemented with educated guesses for a few supplementary parameters. Therefore, it is likely of practical use for many data-poor fisheries on long-lived species (e.g., natural mortality, M < 0.2) (Honey et al. 2010). The ability of this method to identify sustainable yields from simple data input makes DCAC useful as a first-step estimate for an allowable catch level along with other data-poor methods. See: http://nft.nefsc.noaa.gov/ for the NOAA toolbox to perform DCAC analysis (Honey et al. 2010).

Vulnerability analysis

**Productivity and susceptibility analysis of vulnerability** – The Productivity-Susceptibility Analysis of vulnerability (PSA) method is used to assess a stock’s vulnerability to overfishing, based on relative scores derived from life-history characteristics. Productivity, which represents the potential for stock growth, is rated semi-quantitatively from low to high on the basis of the stock’s intrinsic rate of increase (r), von Bertalanffy growth coefficient (k), natural mortality rate (M), mean age at maturity, and other metrics (Patrick et al. 2009; Patrick et al. 2010; Field et al. 2010; Cope et al. 2011; Honey et al. 2010).

To assist regional fishery management councils in determining vulnerability, NMFS elected to use a modified version of a productivity and susceptibility analysis (PSA) because it can be based on qualitative data, has a history of use in other fisheries, and is recommended by several organizations as a reasonable approach for evaluating risk (Patrick et al. 2010). Patrick et al. (2010) evaluated six U.S. fisheries targeting 162 stocks that exhibited varying degrees of productivity and susceptibility, and for which data quality varied. Patrick et al. (2010) found that PSA was capable of differentiating the vulnerability of stocks along the gradient of susceptibility and productivity indices. The PSA can be used as a flexible tool capable of incorporating region-specific information on fishery and management activity. Similar work was conducted by Cope et al. (2011) who found that PSA is a simple and flexible approach to incorporating vulnerability measures into complex stock designations while also providing information helpful in prioritizing stock- and complex-specific management.

**Extrapolation (Robin Hood Method)**

When very limited or no data are available for a stock or specific species in a region, then managers may need to rely on extrapolation methods to inform decisions. Often, low-value stocks are data-poor (Honey et al. 2010). This method is termed the “Robin Hood” approach in Australia because it takes information and scientific understanding in data-rich fisheries and “gives” inferences to the data-poor fisheries (Smith et al. 2009). Data may include: (1) the local knowledge of the fishers and resource users; and/or (2) scientific research and ecosystem understanding from “sister” systems thought to be similar (Honey et al. 2010). Extrapolation from similar systems or related species may offer an informed starting point from which managers can build precautionary management (Honey et al. 2010). In these situations, life-history characteristics, potentially sustainable harvest levels, spawning behavior, and other information can be gleaned from nearby stocks, systems, or related species (Honey et al. 2010).
Decision-making methods

**Decision trees**

Decision trees provide systematic, hierarchical frameworks for decision-making that can scale to any spatial, temporal, or management context in order to address a specific question. A decision tree may be customized to meet any need (Honey et al. 2010). Trees may include: identification of reference points based on stock characteristics and vulnerability (Cope and Punt 2009); fostering of fine-scale, transparent, and local management (Prince 2010); and, estimation and refinement of an appropriate Total Allowable Catch (TAC) level (Wilson et al. 2010).

**Management strategy evaluation**

Management Strategy Evaluation (MSE) is a general modeling framework designed for the evaluation of performance of alternative management strategies for pursuing different objectives (Honey et al. 2010). This approach simulates the fishery’s response to different management strategies (e.g., different TAC levels, seasonal closures, or other effort reductions) (Honey et al. 2010). Assuming sufficient quality data exist, MSE may be useful for assessing the effectiveness of different policy options (Honey et al. 2010).

In addition, a study by Dowling et al. (2008) developed harvest strategies for data-poor fisheries in Australia. Strategies included: (i) the development of sets of triggers with conservative response levels, with progressively higher data and analysis requirements at higher response levels, (ii) identification of data gathering protocols and subsequent simple analyses to better assess the fishery, (iii) the archiving of biological data for possible future analysis, and (iv) the use of spatial management, either as the main aspect of the harvest strategy or together with other measures (Honey et al. 2010).

**Cooperative research and co-management to overcome data-poor situations**

A recent study by Fujita et al. (2010) identified opportunities for cooperative research and co-management that would complement (but not replace) existing top-down fishery regulations. They conclude that management and data collection would improve for some small-scale fisheries if they started: collecting data at the appropriate spatial scales; collecting local information, improving the quality of data, and overcoming constraints on data; providing ecosystem insight from a small/local scale for new and different perspectives; reducing conflicts among fishermen, scientists, and regulators; and improving the responsiveness of fisheries management to local needs. Fujita et al. (2010) suggest that scientists and managers should further develop cooperative strategies (e.g., cooperative research and co-management) and include them in the management framework.

**Effective management of a fishery on a non-native species**

Effective management of a fishery for a non-native species may include:

- Mitigation strategies aimed at eradication, reversing establishment, or maintenance at low abundance, as deemed appropriate and feasible for that particular case,
- Adaptation strategies that allow for recovery of species impacted by the non-native species,
- Containment measures such as fishing at the boundaries of the stock to prevent further spread, and/or
- Provisions to prohibit further introductions of any other alien species.
Appendix 5 – Bycatch reduction approaches

In general, fisheries should address bycatch with the following approaches:

• Monitor bycatch rates (using adequate observer coverage),
• Have some scientific assessment of impacts on bycatch populations
• Incorporate strategies that assure bycatch is minimized, such as:
  o Enforcing effective and appropriate bycatch caps,
  o Closing hotspots or implementing seasonal closures,
  o Promoting effective gear modifications such as BRDs, TEDs, etc.
  o Adopting bycatch-reducing strategies such as night setting,
  o Using the best available management techniques that have been demonstrated in this or a similar system to effectively constrain bycatch rates.

The effectiveness of various bycatch reduction approaches is synthesized from primary literature and reviewed below. To be considered “highly effective”, all required measures and at least one primary measures should be in place.

Seabird sources are Løkkeborg (2008) (general conclusions and Table 3, including percent effectiveness of some modification/region strata) and SBWG 2010 (Annexes 3–8). *Secondary measures may be useful in conjunction with primary measures. Turtle sources are FAO 2009 (Tables 1 and page 79) and Gilman and Lundin (2008) (Table 3). Shrimp trawl modifications sources are Eayers 2007 and Gillet 2008 (Box 14). Sharks and marine mammals from Gilman and Lundin (2008) (Table 3). General information on fishing technologies can be found at http://www.fao.org/fishery/en, and a list of bycatch reduction literature can be found here: http://www.bycatch.org/articles.

Bycatch fees, Compensatory Mitigation Strategies for Marine Bycatch (CMSMB)

Secondary, at best

Not effective. "We conclude that, overall, CMMB has little potential for benefit and a substantial potential for harm if implemented to solve most fisheries bycatch problems. In particular, CMMB is likely to be effective only when applied to short-lived and highly fecund species (not the characteristics of most bycatch-impacted species) and to fisheries that take few non-target species, and especially few non-seabird species (not the characteristics of most fisheries). Thus, CMMB appears to have limited application and should only be implemented after rigorous appraisal on a case-specific basis; otherwise it has the potential to accelerate declines of marine species currently threatened by fisheries bycatch" (Finkelstein, Bakker et al. 2008). May be useful, but only as a complementary measure (Žydelis, Wallace et al. 2009).

#### Bait change

Primary

Use of fish instead of squid.

#### Deep setting

Primary

Set gear deeper than turtle abundant depths (40–100m).

#### Fish bait hooking

Primary

Single hooking fish bait instead of threading hook through bait multiple times.

#### Temporal changes

Primary

Reduce soak time and haul during daylight.

#### Lights on gear

Primary

Use of intermittent flashing light sticks instead of continuous use non-luminous gear.

#### Handling and release practices

Secondary

To reduce mortality of caught turtles.

**Seabirds (albatrosses and petrels)**

- **Best**
  - No single solution to avoid incidental mortality of seabirds in demersal longline fisheries. No combination specified; assume streamers, weighted and night setting, or Chilean longline method (vertical line with very fast sink rates—considered effective even without other measures; widely used in South American waters and SW Atlantic). Best practices are followed for line setting and hauling (e.g., SRWG 2010).

- **Streamer/scarer lines**
  - Primary
  - Effective, but must be used properly (streamers are positioned over sinking hooks). Better when combined with, e.g., night setting, weighting, or offal control.

- **Weighted lines**
  - Primary
  - Must be combined with other measures, especially streamers, offal control and/or night setting.

- **Night setting**
  - Primary
  - Same as pelagic.

- **Haul curtain (reduce bird access when line is being hauled)**
  - Secondary
  - Can be effective, but must use strategically as some birds become habituated. Must be used with other measures.

- **Offal discharge control (discharge homogenized offal at time of setting)**
  - Secondary
  - Must be used in a combo, e.g., with streamers, weighting, or night setting.

- **Side setting**
  - Secondary
  - Insufficiently researched; there have been operational difficulties on some vessels.

- **Hook design, olfactory deterrents, underwater setting chutes, blue-dyed bait, thawed bait, use of line setter**
  - Insufficiently researched. Blue-dyed bait, thawed bait, and use of line setter not relevant in demersal gear.

- **Turtles, sharks, mammals, other finfish, shellfish**
  - See pelagic longlines

**Trawl**

---

92
### Seabirds (albatrosses and petrels)

| Best | Little work has been done on seabird bycatch mitigation in trawl fisheries (pelagic and demersal). There is no single solution to avoid incidental mortality of seabirds in trawl fisheries. The most effective approach is offal discharge and discards control, through full retention of all waste or mealing (the conversion of waste into fish meal reducing discharge into sump water) plus streamer lines. Effectiveness of other offal control measures such as mincing and batching is not clear. |

### Limited waste control

| Minimum requirement for + modifier | No discharge of offal or discards during shooting and hauling. |

### Reduce cable strike through bird scaring wires or snatch block

| Primary | Scarers recommended even when offal/discard management is in place. Snatch block recommended on theory. |

### Reduce net entanglement through net binding, net weights, net cleaning

| Recommended on theory. |

### Net jackets

| Not recommended. |

### Reduced mesh size, acoustic scarers, warp scarers, bird bafflers, cones on warp cables

| Effectiveness not yet established. |

### Turtles

| Turtle excluder device (TED) | Any modification to the trawl to reduce the capture of turtles, principally in tropical/subtropical shrimp trawls. Typically a grid or large-hole mesh designed to prevent turtles from entering the codend. The only designs approved for use in the US warm-water shrimp fisheries are hard TEDs (i.e., “hooped hard TEDs” such as NMFS, Coulon and Cameron TEDs, “single grid hard TEDs” such as the Matagorda, Georgia, or Super Shooter TED, and the Weedless TED) and the Parker Soft TED (the latter only in offshore and inshore waters in Georgia and South Carolina). Hard TEDs that are not approved for use in the shrimp fisheries are used in the Atlantic summer flounder bottom trawl fishery. TEDs must be used in conjunction with escape hatches, which also vary in size and design. More details on TED/hatch designs and US regulations can be found in Eayers (2007). |

### Sharks

| TEDs generally allow large animals to escape, e.g., sharks (Belcher and Jennings 2010). Highly variable depending on net type and TED used. BRD made little difference (fisheye). |

### Marine mammals

| TED/BRD | Grids generally allow large animals to escape. |

### Other finfish
## Bycatch reduction device (BRD): Catch separators

A BRD is any modification designed principally to exclude fish bycatch from shrimp trawls. Catch separator designs include hard grids (e.g., Nordmore grid) and soft mesh panels attached at an angle inside the trawl net as well as the Juvenile and Trash Excluder Device (JTED), which has a grid/mesh design partially covering the inside of the trawl net. Hard grids are generally seen as more effective than soft panels. Effectiveness of JTED unknown.

## BRD: Active swimmer escape hatches

Designed for strong-swimming fish to actively escape (shrimp are more passive swimmers). Most are located in the codend (e.g., fisheye and fishbox) although others can be in the body of the trawl (square mesh window, composite square mesh panel, radial escape section).

## BRD: Square-mesh codend

Square mesh stays open under tow (unlike diamond mesh).

## BRD assist

E.g., the cone. Stimulates fish to swim forward through escape hatches like the fisheye, square mesh window or radial escape section.

## Coverless trawl

Inclusion of increased mesh sizes in the upper wings and upper netting panel immediately behind the headrope crown, coupled with reduced headline height, encourages the escape of fish species such as haddock and whiting in and around the mouth of the trawl.

## Rigging modification

Triangular/diamond-shaped cut in the top of the codend (e.g., flapper), changes to ground chain settings, headline height reduction, a length of twine stretched between the otter boards to frighten fish, large mesh barrier across trawl mouth and large cuts in the top panel of the net ahead of the codend.

## Semi-pelagic rigging

Avoid contact with seabed.

## Trawl separator (Rhule trawl)

Reduces cod catch in haddock trawls by separating catch and releasing cod from the net.

## Shellfish

TEDs generally allow large animals to escape (jellyfish). Downward facing TEDs may also allow benthic invertebrates to escape.

## BRD e.g., Nordmore grid

Effective for jellyfish?

## Rigging modification

Longer sweeps between the otter board and trawl can reduce invertebrate bycatch.

## Semi-pelagic rigging

Avoid contact with seabed.

## Other

BRD

Seahorses, sea snakes in Australian prawn fisheries.

## Gillnet

Seabirds

Less research than for trawls.

Visual and acoustic alerts

- Pingers may also reduce seabird bycatch (1 study in Lokkeborg 2008).

## Turtles

Use lower profile nets

Primary

Reduces entanglement as the net is stiffer. Good for both demersal and drift nets.

Use of tie-down ropes

Negative

Creates slack in the net, increasing chances of entanglement (rather than gilling).

Set nets perpendicular to shore

- Insufficient research. May reduce interactions with nesting females.

Use deterrents

- Insufficient research. Pingers, shark silhouettes, lights or chemicals.

Deep setting

- Insufficient research. Avoid upper water column (above 40m).
Sharks
Unknown

**Marine mammals**

| Pingers | Acoustic devices to keep cetaceans (and possibly pinnipeds) away from nets. Effectiveness appears to vary considerably depending on fishery and cetacean species: [http://cetaceanbycatch.org/pingers_effectiveness.cfm](http://cetaceanbycatch.org/pingers_effectiveness.cfm) |

**Shellfish**

| Weak buoy lines | |

| Mesh size | |

**Purse Seine**

| Seabirds | Not problematic |

**Turtles**

| Avoid turtles | Primary | Avoid encircling turtles. Restrict setting on FADs, logs and other debris. |

| Use of modified FAD designs | - | Insufficient research. |

**Sharks**

| Avoid sharks | Primary | Avoid restrict setting on FADs, logs, other debris and whales. Avoid hotspots. |

| Shark repellants | - | For deployment on FADs. Insufficient research. |

**Marine mammals**

| Backdown maneuver, Medina panel, deploy rescuers | Primary | |

| Avoid mammals | | Restrict setting on mammals. |

**Other finfish**

| Sorting grids | - | Insufficient research. |

| Avoid finfish | | Restrict setting on FADs. |

**Shellfish**

| Not problematic | |

**Pots and traps**

| Turtles | |

| BRDs | Primary | E.g., Diamondback terrapins in Floridian blue crab pot fishery (Butler and Heinrich 2005). |

**Marine mammals**

| Weak lines | Primary | E.g., northern right whales, NE lobster fishery. |

**Finfish, invertebrates**

| BRDs | Primary | |

### Appendix 6 – Impact of fishing gear on the substrate

In order to assess fisheries for habitat impacts under the Seafood Watch ® criteria, we developed a matrix to help determine the potential impacts that different fishing gear may have on various habitat...
types. The matrix was developed based on similar work done by the New England Fisheries Management Council (NEFMC 2010) and the Pacific Fisheries Management Council (PFMC 2005).

The NEFMC (2010) created a “Swept Area Seabed (SASI) model” that assessed habitat susceptibility and recovery information. Susceptibility and recovery were scored (0–3) based on information found in the scientific literature and supplemented with professional judgment when research results were deficient or inconsistent.

“Vulnerability was defined as the combination of how susceptible the feature is to a gear effect and how quickly it can recover following the fishing impact. Susceptibility was defined as the percentage change in functional value of a habitat component due to a gear effect, and recovery was defined as the time in years that would be required for the functional value of that unit of habitat to be restored (ASFMC 2010).”

The PFMC (2005) created a similar habitat sensitivity scale (0–3) that represents the relative sensitivity of different habitats to different gear impacts. The sensitivity of habitats from the PFMC (2005) was based on actual impacts reported in the scientific literature.

The relative impacts by gear and habitat type used for the Seafood Watch® matrix were based on the sum of sensitivity and recovery values from tables developed by the NEFMC (2010) (substrates) and the PFMC (2005) (biogenic). The NEFMC (2010) excluded deep-sea corals with extreme recovery times. The values for deep-sea corals in this matrix are the sum of the sensitivity and recovery scores from PFMC (2005). Other biogenic habitats that were not included in the NEFMC (2010) data tables include: seagrass, sponge reefs (rather than individual sponges) and maerl beds. Due to the slow recovery and importance of these habitat types, they have been given the same value as coral and sponge habitats, all of which are listed as “biogenic”.

Hall-Spencer and Moore (2000) examined the effects of fishing disturbance on maerl beds. Maerl beds are composed of a calcareous alga and form complex habitats with a high degree complexity. The associated species assemblages have high diversity (Hall-Spencer and Moore, 2000). Hall-Spencer and Moore (2000) showed that four years after an initial scallop-dredging disturbance had occurred, some fauna, such as the bivalve Limaria hians, had still not re-colonized the trawl tracks. Similarly, work by Sainsbury et al. (1998; in Kaiser et al. 2001) suggests that recovery rates may exceed fifteen years for sponge and coral habitats off the western coast of Australia.

Hydraulic clam dredges are rated as a high concern according to Seafood Watch®. There are very few studies on the impact of this gear type, so we have relied on expert opinion (NEFMC 2010). Hydraulic clam dredges are used primarily in sand and granule-pebble substrates because they cannot be operated in mud or in rocky habitats (NEFMC 2010). This gear type is effective at pulverizing and/or removing solids and flattening out seafloor topography (NEFMC 2010). In addition, the habitats where this gear type is used are very susceptible to hydraulic dredges; recovery is moderate on average (NEFMC 2010). This leads Seafood Watch® to rate hydraulic dredges as “high concern.” Hydraulic dredges do not operate on deep-sea coral or other biogenic habitats.

Neckles et al. (2005) found significant differences in eelgrass biomass between disturbed and reference sites up to seven years after dragging. The authors projected that it would require a mean of 10.6 years for eelgrass shoot density to recover in areas of intense dragging.
Demersal seines were not evaluated in the reports by Fuller et al. (2008), Chuenpagdee et al. (2003), NEFMC (2010) or PFMC (2005). Demersal seines include: Danish seines, Scottish fly-dragging seines and pair seines. These seines are similar to some bottom trawl gear in that they have a funnel shaped net with a groundrope. They are generally hauled by wires or ropes, and although they are lighter than some bottom trawl gear, they create habitat disturbance (Rose et al. 2000; Thrush et al. 1998; Valdemarason and Suuronen 2001). A review of trawling impacts by Jones (1992) grouped bottom trawling, dredges and Danish seines together as having similar impacts on the benthos when assessing the environmental effects of bottom trawling. However, studies have demonstrated Danish seines to have less impact on the substrate compared to bottom trawls (Gillet 2008). Therefore, in our matrix they are given an intermediate score as more damaging than bottom longlines and bottom gillnets, but less damaging than bottom trawls. Beam trawls were also not included in the reports, but were considered to be similar to otter trawls.

The matrix developed from the sources referenced above is shown on the next page. For use in evaluating the Fisheries Criteria, these data have been summarized into categories (low impact, moderate, moderate-severe, severe, and very severe) to simplify use of the table.
Habitat impacts matrix: Relative impacts by gear and habitat type.

* Shrimp trawls tend to be lighter than bottom otter trawls for fish and do not need to touch the seabed to be effective.

** Most biogenic habitats (macroalgae, cerianthid anemones, polychaetes, sea pens, sponges, mussel and oyster beds) are incorporated into the scores for each substrate/gear combination in the table. NEFMC 2010 specifically excluded deep-sea corals. The numbers for deep-sea corals in this matrix are the sum of the sensitivity and (standardized) recovery scores in PFMC 2005. Other biogenic habitats that were not included in the NEFMC data tables include seagrass meadows, sponge reefs (rather than individual sponges) and maerl beds. Use the ‘deep-sea corals’ column for these habitats.

*** Scores not determined for hydraulic dredges in these habitats as the gear is assumed to not operate in them (NEFMC 2010).

**** NEFMC 2010 groups bottom longlines and gillnets as ‘fixed gear’ (not shown in table). These scores have been disaggregated here for substrate habitats only by adding 0.4 to the aggregated score for gillnets and subtracting 0.4 for longlines, based on the relative impacts shown in PFMC 2005 (i.e. that gillnets are generally more damaging than longlines).

The values above are the sum of sensitivity and recovery values in tables from Section 5.2 in Part 1 of (NEFMC 2010) (substrates) and Tables 4 and 5 in Appendix C, Part 2 of (PFMC 2005) (biogenic). Gear types in black are from the Swept Area Seabed Impact (SASI) model used for the NEFMC EFH process (NEFMC 2010). Gear types in red are derived from those in black. Substrate types are self-explanatory except that mud includes clay-silt and muddy sand, and boulder includes rock. The energy regime is used here as a proxy for natural disturbance, with a cutoff between low and high stability at 60m depth. Most biogenic habitats (macroalgae, cerianthid anemones, polychaetes, sea pens, sponges, mussel and oyster beds) are incorporated into the scores for each substrate/gear combination in the table. NEFMC (2010) specifically excluded deep-sea corals with extreme recovery times. The numbers for deep-sea corals in this matrix are the sum of the sensitivity and (standardized) recovery scores from PFMC (2005). Other biogenic habitats that were not included in the NEFMC data tables include seagrass meadows, sponge reefs (rather than individual sponges) and maerl beds. Use the “deep-sea corals” column for these habitats.
Appendix 7 – Gear modification table for bottom tending gears

Spatial protection

Reducing the footprint of fishing through spatial management can be one of the most effective ways to mitigate the ecological impact of fishing with habitat-damaging gears (Lindholm et al. 2001; Fujioka 2006). The relationship between gear impacts, the spatial footprint of fishing and fishing effort (i.e., frequency of impact) is complex (Fujioka 2006) and cannot be quantified precisely in Seafood Watch® assessments. Nevertheless, criteria should acknowledge the benefits of conservative habitat protection efforts by adjusting the habitat score. Thresholds for adjusting the habitat score due to habitat protection from the gear-type used in the fishery (50% protected to qualify as “strong mitigation” and 20% protected to qualify as “moderate mitigation”) are based on recommendations for spatial management found in the scientific literature as noted in Auster (2001). Auster recommends use of the precautionary principle when a threshold level of 50% of the habitat management area is impacted by fishing, with a minimum of 20% of regions in representative assemblages and landscape features protected in MPAs in order to minimize impacts on vulnerable species and sensitive habitats.

The table below gives examples of gear modifications that are believed to be moderately effective at reducing habitat impacts based on scientific studies. This table will be continually revised as new scientific studies become available. The main sources for the current table are He (2007) and Valdemarsen, Jorgensen et al. (2007).

<table>
<thead>
<tr>
<th>Gear</th>
<th>Modification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Otter Trawls</td>
<td>Semi-pelagic trawl rigging (trawl doors, sweeps and bridles off the bottom, also includes modifications such as short bridles and sweeps—most commonly used for shrimp, nephrops and other species that are not herded by sand clouds and bridles due to poor swimming ability)</td>
</tr>
<tr>
<td></td>
<td>Quasi-pelagic trawl rigging/sweepless trawls (trawl doors remain in contact with the seafloor, remaining gear largely off the bottom, e.g., whiting in New England, flatfish in Alaska, red snapper in Australia)</td>
</tr>
<tr>
<td></td>
<td>Lighter ground gear (e.g., fewer bobbins)</td>
</tr>
<tr>
<td></td>
<td>Use of rollers instead of rockhoppers</td>
</tr>
<tr>
<td></td>
<td>Trawl door modifications such as high aspect (smaller footprint), cambered (generally for fuel efficiency) or soft doors (e.g., self-spreading ground gear)</td>
</tr>
</tbody>
</table>
